DISSERTATION THIRD:
EXHIBITING A GENERAL VIEW
OF THE
PROGRESS OF CHEMICAL PHILOSOPHY,
FROM THE EARLY AGES TO THE END OF THE
EIGHTEENTH CENTURY.

By WILLIAM THOMAS BRANDE,
SECRETARY OF THE ROYAL SOCIETY OF LONDON, FELLOW OF THE ROYAL SOCIETY OF EDINBURGH,
PROFESSOR OF CHEMISTRY IN THE ROYAL INSTITUTION OF GREAT BRITAIN, AND
PROFESSOR OF CHEMISTRY AND MATERIA MEDICA TO THE
SOCIETY OF APOTHECARIES OF THE
CITY OF LONDON.

DISSERTATION THIRD.

SECTION I.

GENERAL VIEW OF THE PROGRESS OF CHEMICAL SCIENCE, FROM THE EARLY AGES TO
THE END OF THE SEVENTEENTH CENTURY.

THE phenomena of the universe present a series of changes, of which the regularity and harmonious succession excite the surprise of superficial observers, and awaken the admiration and attention of the philosophic mind.

These changes are either accompanied by visible motion susceptible of measurement, and relate to the exterior forms and mechanical characters of bodies, or they depend upon the mutual agencies of the elementary principles of matter, upon its composition, upon its susceptibility of acquiring new properties by entering into new combinations.

The investigation of the former phenomena belongs to the mechanical philosopher ; to trace the causes of the latter, and to discover the laws to which they are obedient, is the business of chemical science.¹

¹ *Definitions of Chemistry*.—"La Chymie est un art qui enseigne à separer les differentes substances qui se rencentrent dans un mixte." (L'Emery, *Cours de Chymie*.)

"Chemistry is that science which examines the constituent parts of bodies, with reference to their nature, proportions, and method of combination." (Bergman, *Essay on the Usefulness of Chemistry*.)

"Chemistry is the study of the effects of heat and mixture, with a view of discovering their general and subordinate laws, and of improving the useful arts." (Black, *Lectures*.)

"La Chimie est une science qui apprend à connaitre l'action intime et réciproque de tous les corps de la nature, les uns sur les autres. Par les mots *action intime*, et *reciproque*, cette science est distinguée de la

Chemistry, considered as a branch of scientific inquiry, is not of ancient date.¹ Founded upon principles deduced from experiment and observation, centuries were

physique experimentale, qui ne considère que les propriétés extérieures des corps doués d'un volume, et d'une masse qu'on peut mesurer, tandis que la Chimie ne s'attache qu'aux propriétés intérieures, et n'agit que sur des molécules, dont le volume et la masse ne peuvent pas être soumis aux mesures et aux calculs." (Fourcroy, *Système des Connoissances Chimiques*, Vol. I. p. 4.)

"Die Chemie ist eine Wissenschaft die uns die wechselseitigen Wirkungen der einfachen Stoffe in der Natur, die Zusammensetzung der Körper aus ihnen und nach ihren verschiedenen Verhältnissen, und die Art und Weise kennen lehrt, sie zu trennen, oder sie wieder zu neuen Körperarten zu verbinden." (Gren. *Systematisches handbuch der Chemie*, p. 1. Halle, 1794.)

"Chemistry is that science which treats of those events or changes in natural bodies, which are not accompanied by sensible motions." (Thomson, *System of Chemistry*, fifth edition, p. 2.)

Most of the substances belonging to our globe are constantly undergoing alterations in sensible qualities, and one variety of matter becomes, as it were, transmuted into another. Such changes, whether natural or artificial, whether slowly or rapidly performed, are called chemical;—thus the gradual and almost imperceptible decay of the leaves and branches of a fallen tree exposed to the atmosphere, and the rapid combustion of wood in our fires, are both chemical operations.

"The object of chemical philosophy is to ascertain the causes of all phenomena of this kind, and to discover the laws by which they are governed." (Davy, *Elements of Chemical Philosophy*, p. 1.)

In the edition of Johnson's *Dictionary*, now publishing by the Rev. H. J. Todd, the erroneous and antiquated definition of Boerhaave is very improperly retained. "An art whereby sensible bodies contained in vessels, or capable of being contained therein, are so changed by means of certain instruments, and principally fire, that their several powers and virtues are thereby discovered, with a view to philosophy or medicine."

The derivation of the word Chemistry can scarcely be said to have been ascertained. The most plausible guesses are the following: from *χυν* to melt, or *χυμος* juice; from *kema*, an oriental word signifying *black*; from *χμης*, the name of a person eminently skilled in the sciences; from *Chémi*, the Coptic name of Egypt, where the art is supposed to have had its rise.

According to Bryant (*Ancient Mythol.*), it is derived from *chemia*, and that word from *Cham*.

The Rev. Mr Palmer, Professor of Arabic at Cambridge, has given the following etymology: "Al-chemy, or more properly Al-kemy, the knowledge of the substance or composition of bodies, so named from the substantive (Kyamon), that is, the substance or constitution of any thing; from the root (Kama). Golius. *Lexicon*." (Thomson's *Chemistry*, 5th edit. p. 4. Note.)

Conversing upon this subject with Dr Thomas Young, he remarked, that the Egyptians probably neither knew nor cared much about the composition of bodies; and that the term Chemistry, as referring to the secret art of transmutation, was probably derived from the Coptic root *lhems* or *chems*, signifying *obscure*, *dark*. The German word *geheim*, *secret*, he said, was perhaps of the same root.

"Hæc ars varia accepit nomina, nam omnium primò dicta fuit *ἐρχη ποιητική*, et antiquis illis temporibus per hanc vocem significabant artem vilia metalla in aurum convertendi, et ejus artifices *ποιηταί* vocari Zozimus dicit. Veteres Ægyptios hanc artem *Chimoot* vocasse Josephus Scaliger ibi ostendit, sed postea Græci hanc artem *χρυσοποιαν* dixerunt, Arabibus vero, *Alchemia*." (Boerhaave, *Institutiones Chemicæ*.)

¹ "Tout ce qu'on a dit de l'antique origine de la Chimie, sur les premiers hommes qui ont travaillé les métaux, taillé et poli les pierres dures, fondu les sables, dissous et cristallisé les sels, ne montre à un esprit exact et sévère qu'une vaine et ridicule prétension, semblable à cette par laquelle on voudrait reconnoître

consumed in their accumulation and systematic arrangement ; but, as an art, chemistry is readily traced to periods of remote antiquity ; for it is obvious that the chemical changes of matter must have been rendered subservient to the wants of mankind in the earliest ages of the world.

Metallurgy is among the most ancient of the arts, and Tubal Cain, the instructor of workers in iron and brass, has thence been called the inventor of chemistry. Others have preferred the claims of Noah, to whom the invention of wine has been attributed ; but these, and other arts alluded to in Sacred Writ, such as dyeing, gilding, and embalming, which have been adduced as instances of chemical knowledge in the time of Moses, prove nothing more than that such processes were practised at that period, independent of each other, and quite unconnected by the slightest reference to general principles.¹

It is probable that the early mythological systems of the Egyptians contained some allusions to the chemical changes of matter, and to them the first speculations on the art of transmutation have been attributed. Hermes, or Mercurius Trismegistus, the favourite minister of the Egyptian king Osiris, has been celebrated as the inventor of this art, and the first treatise upon it has been attributed to Zosymus, of Chemnis or Panopolis in Egypt. The inhabitants of Sydon and Tyre, those renowned seats of the commerce of the ancient world, seem to have been skilled in some chemical manufactures ; they made glass and artificial gems, and excelled in dyeing purple.

Egypt maintained its superiority in arts until the invasion of Alexandria by the Saracens, when the celebrated library collected by the Ptolemies, with great diligence and at enormous expence, was burned by the orders of Caliph Omar.² The alchemical

les élémens de la géométrie dans l'ouvrage grossier du sauvage qui use les fragmens du rocher, qui leur donne des formes à peu près régulières pour les rendre utiles à ses premiers besoins." (Fourcroy, *Discours Préliminaire*.)

¹ " Si l'on examine cependant avec courage et sans préjugé toutes les preuves qu'on a réunies pour établir l'existence de la Chimie chez les Egyptiens, après avoir reporté son origine aux premiers âges du monde et aux premiers travaux où les hommes ont employé le feu comme agent, on reconnaît bientôt que tirées uniquement des produits employés dans leurs constructions diverses, elles peuvent toutes annoncer des arts ou des procédés de fabrique plus ou moins avancés, mais rien qui tienne à des notions générales tirées de ces arts, comparés rien qui dépende d'une doctrine suivie, rien enfin qui puisse donner une idée d'une véritable science." (Fourcroy, *Disc. Prélim.*)

² " Qui his scriptis parcendum esse negabat, quippe quæ inutilia essent, si eorum dogmata Alcorano congruerent, noxia vero, si ab illo dissentirent." (Bergman, *De primordiis Chemia*.)

works had been previously destroyed by Diocletian in the fourth century, lest the Egyptians should acquire by such means sufficient wealth to withstand the Roman power. On the present occasion, about seven hundred thousand volumes were seized, which we are told supplied six months' fuel for forty thousand baths, that contributed to the health and convenience of the populous capital of Egypt.

When philosophy declined in Egypt and in the East, Greece became the principal seat of learning and of the arts ; but the systems of their early philosophers, of Thales¹ the founder of the Ionic sect, of Anaximander, and Anaximenes, breathe the sentiments of the Egyptian schools. By Thales water was considered as the source of all things, as the universal element. The opinions of Anaximander, in themselves unintelligibly obscure, received some elucidation from his successor Anaximenes; they regarded air and fire as the first rudiments of matter.

The result of the Macedonian war introduced Grecian philosophy into Italy, and the doctrines of Plato,² and Aristotle, and Theophrastus, prevailed in the school of Rome.

Among the early Roman philosophers, Lucretius³ stands preeminent ; but his opinions had been formed at Athens, in the Stoic school of Zeno, and he early imbibed the doctrines of Empedocles and Epicurus, which are expounded with superior genius and admirable ingenuity in his masterly poem on the *Nature of Things*.

The celebrated Natural History of the elder Pliny, written in the first century of the Christian era, contains an account of the rise and progress of the arts and sciences previous to that period, which, though not always accurate, often obscure, and sometimes unintelligible, abounds in instructive documents and interesting remarks. It is written, not in the elevated, refined, and elegant style of the Augustan age, but in the language of the laborious and liberal historian, frequently led by the extent of his inquiries to subjects which he is incompetent to manage, and upon which his opinions are incorrect, his conjectures vague, his assertions ill-founded.

The origin of many of the follies and mysteries of Alchemy may perhaps be referred with most propriety to the *New Platonists*, whose rise marked the declining age of learning towards the end of the third century of the Christian era. These philosophers, celebrated for their metaphysical disputes and superstitious notions, credited the existence of demons and spirits, with whom they claimed familiar intercourse. Ne-

¹ 600 years B. C.

² 340 years B. C.

³ 50 years B. C.

glecting useful knowledge, they exhausted their strength in verbal disputes, and in attempts to discover the secrets of the invisible world; thus gradually converting the study of philosophy into that of demonology and magic. "Several of these masters," says Gibbon, "Ammonius, Plotinus, Amelius, and Porphyry, were men of profound thought and intense application: but, by mistaking the true object of philosophy, their labours contributed much less to improve than to corrupt the human understanding."

Porphyry died about the time of Diocletian's abdication. The life of his master, Plotinus, which he composed, gives a complete idea of the genius of the sect, and the manners of the Professors. This curious piece is inserted in Fabricius. (*Bibliotheca Græca*, Tom. IV.) When the cultivated part of Europe was overwhelmed by the barbarous nations, all records of arts and sciences possessed by the Greeks, and by their Roman successors, were swept away in the general destruction, and now the Arabians became the protectors of philosophy, and the promoters of its pursuits. To them, Chemistry, regarded as a distinct branch of experimental philosophy, owes its origin, and several circumstances co-operated to render its progress rapid, which are important in their relation to the subsequent advances of the science. Among these the mysteries of Alchemy, so well adapted to the genius of that age and people, are the most remarkable. Of this occult art, the two leading objects were the *transmutation* of common metals into gold and silver, and the discovery of the *universal medicine*, which, by the removal and prevention of disease, should confer immortality upon the possessors of the secret.

The origin of these chimerical notions has been variously accounted for. The idea of transmutation may plausibly be referred to the various processes to which natural bodies were submitted by the astrological experimentalists of the seventh and eighth centuries. Observing the change of properties in metallic ores by exposure to heat, and the production of malleable and useful metals from their brittle and useless compounds, it is not surprising that superficial observation and incorrect reasoning should lead to a belief in their production and transmutation; and such speculations, not without apparent foundation, holding out attraction to the ambitious, and hope to the needy, would soon excite notice and command followers. That this was the case, the records of those times amply testify.

The pursuit of the other object may be referred to the success attending the medical employment of many of the chemical preparations. Pharmacy was becoming enriched by the introduction of chemical compounds; and remedies for diseases, before deemed incurable, were occasionally discovered among the products of

the furnace. Hence, perhaps, the possibility of the existence of an universal remedy might occur to those under the infatuations of the black art.

The earliest of the true Alchemists, whose name has reached posterity, is Geber,¹ supposed to have been an Arabian prince of the seventh century. The works attributed to Geber, several of which have been published in Latin translations by Golius, and others in English by Russell, are numerous and curious. They abound in the cant and jargon of the hidden art. Some have asserted his pretensions to the possession of the universal medicine, for he speaks of curing disease. But this seems a mere metaphorical expression, relating to transmutation. "Bring me," says he, "the six lepers, that I may cleanse them;" by which he doubtless would imply the conversion of silver, mercury, copper, iron, tin, and lead, into gold,—there being only these seven metals known at that period. Dr Johnson supposes that the word *Gibberish*, anciently written *Geberish*, was originally applied to the language of Geber and his tribe.

The elder Mesue and Avicenna,² physicians of the ninth and tenth centuries, have given some account of the Chemistry of their age, but their works relate chiefly to medicine. Indeed, it is probable that the writings now extant in the name of the former are spurious.

The twelfth, thirteenth, and fourteenth centuries, abound in writers on the secrets of Alchemy; and the happy few to whom fate and metaphysical aid had granted the discovery of the great secret, assumed the title of *adepts*, a character which required to be sustained by superior feats of deception and duplicity.

About this period, several circumstances happily concurred, favourable to the diffusion of learning and the arts, which began again to dawn in Europe with promising splendour.

¹ "Primus omnium Arabum post Græcos est Geber, cui dant titulum Arabis. Alii dicunt eum fuisse regem, unde *rex Geber Arabs*, dici solet; sed *Leo Africanus* qui Græcus fuit et multa descripsit ex antiquis Arabibus, dicit, Gebrum illum natione Græcus fuisse, sed derogasse suam religionem, et se dedisse Mahomedæ religioni Arabum, et vixisse septimo seculo." (Boerhaave.)

Geber was also a physician and astronomer. The following are the principal works on Chemistry which have been attributed to him: *De Alchemia*,—*De summa perfectione Metallorum*,—*De Lapide Philosophico*,—*De inveniendi arte Auri et Argenti*. These, and some other works bearing his name, whether genuine or not, furnish good specimens of the early alchemical writings.

² Avicenna introduced several important drugs into the *Materia Medica*; and the art of making sugar has been enumerated among his discoveries, although, doubtless, of earlier date.

The extravagant expeditions of the Crusaders tended, in these respects, to the most extensive, beneficial, and permanent consequences. In their progress to Palestine, these ardent followers of the Cross traversed countries which, compared with their own, were cultivated, civilized, and refined. Their minds and manners were thus enlarged and improved, and new customs and institutions attracted their notice.

In Constantinople, then the largest and most magnificent of European cities, some traces of ancient elegance and refinement were still to be found, and many of the natural products and of the manufactures of the East were offered to their notice.¹

We accordingly discover in these superstitious and enthusiastic expeditions the source of many improvements, which afterwards raised Europe to the highest rank among nations; which tended to dispel barbarism, to mitigate the fury of war, and to extend commerce; and which ultimately led to the cultivation of the useful and fine arts, and to the diffusion and exaltation of science.

Another event occurred about this period, which miraculously facilitated the acquisition and propagation of learning, namely, the invention of printing, which, as it were by superhuman mediation, advanced so rapidly to perfection, that the finest specimens of typography are to be found among the early efforts of the art. It was introduced into England by the Earl of Rivers, in the reign of Edward IV.²

Of the earlier writers on Chemistry, no one is more deserving notice than the celebrated Roger Bacon, a native of Somersetshire, who flourished in the thirteenth century. His writings, though troubled and polluted by the reigning absurdities of Alchemy, contain many curious facts and judicious observations. To him the discovery of gunpowder has, with all appearance of justice, been attributed.³ "From saltpetre and other ingredients," he says, "we are able to form a fire which will burn to any distance." And again, alluding to its effects, "a small portion of matter, about

¹ "The first and most obvious progress was in trade and manufactures,—in the arts, which are strongly prompted by the thirst of wealth, the calls of necessity, and the gratification of the sense or vanity. Among the crowd of unthinking fanatics, a captive or a pilgrim might sometimes observe the superior refinement of Cairo and Constantinople. The first importer of windmills was the benefactor of nations; and if such blessings are enjoyed without any grateful remembrance, history has condescended to notice the more apparent luxuries of silk and sugar, which were transported into Italy from Greece and Egypt." (Gibbon, *General consequences of the Crusades*, Vol. XI. p. 289. Edit. 1813.)

² Hume. Edward V.

³ Watson's *Chemical Essays*, Vol. I.

It has been by some imagined, that Roger Bacon invented the air-pump; but the idea rests upon very doubtful expressions. (Boerhaave, *Instit. Prolegom.*)

the size of the thumb, *properly disposed*, will make a tremendous sound and corruscation, by which cities and armies might be destroyed." And again, in the same work, is a passage which, though somewhat enigmatical, is supposed to divulge the secret of this preparation. "Sed tamen salis petræ, *luru mone cap urbre*, et sulphuris, et sic facies tonitrum si scias artificium." The anagram is convertible into *carbonum pulvere*. Such are the claims of Roger Bacon to a discovery which soon changed the whole art of war.

The works of Bacon most deserving perusal are the *Opus Majus*, edited by Dr Jebb in 1733; and his *Epistola de secretis Operibus Artis et Naturæ, et de nullitate Magiæ*. Paris, 1532. The former, addressed to Pope Clement IV., breathes sentiments which would do honour to the most refined periods of science, and in which many of the advantages likely to be derived from that mode of investigation insisted upon by his great successor Chancellor Bacon, are anticipated.

Raymond Lully, Arnold of Villanova,¹ John de Rupescissa, and Isaac and John of Holland,² were Alchemists of the thirteenth, fourteenth, and early part of the fifteenth century. Their writings are extremely numerous; and they each treat of the philosopher's stone, and other secrets of the occult science.

Basil Valentine of Erfurt, who wrote towards the end of the fifteenth century, is deserving of more attention, and ranks among the first who introduced metallic preparations into medicine. In his *Currus Triumphalis Antimonii*,³ after setting forth the chemical preparations of that metal, he enumerates their medicinal effects. According to the notions of the age, he boasts of supernatural assistance; and his work furnishes a good specimen of the controversial disputes between the chemical physicians and

¹ Raymond Lully was born in Majorca in 1236, and Villanova in Provence in 1235. Their writings are as obscure as they are voluminous.

² "Sequuntur nunc Johannes et Isaacus Hollandus, pater et filius, qui diffusissimo sermone et magne eloquentiâ scripserunt, et si unum vel alterum arcanum exceperis pulcherrima experimenta fecerunt de sanguine et urinâ humanâ, quæ Helmontius postea et Boyleus pro recentioribus inventis habuerunt." (Boerhaave.)

³ It is probable that the word Antimony was first used by Basil Valentine. Tradition relates, that having thrown some of it to the hogs, after it had purged them heartily, they immediately fattened; and, therefore, he imagined, that his fellow monks would be the better for a like dose, they having become lean by fasting and mortification. The experiment, however, failed, and they died; whence the medicine was called *Anti-moine*.

He published several other works besides the *Currus Triumphalis Antimonii*. See Chalmers's *Biographical Dict.*

those of the school of Galen,—the former being attached to active remedies, the latter to more simple and inert medicines. The *Chariot of Antimony* opens with the most pious exhortations to prayer and contemplation, to charity and benevolence. But the author, soon forgetting himself, breaks out in the following strain of virulent invective. “Ye wretched and pitiful medicasters, who, full of deceit, breathe out I know not what Thrasonick brags;—infamous men, more mad than Bacchanalian fools! who will neither learn, nor dirty your hands with coals! you titular doctors, who write long scrolls of receipts; you apothecaries, who with your decoctions fill pots no less than those in princes’ courts, in which meat is boiled for the sustenance of some hundreds of men; you, I say, who have hitherto been blind, suffer a collyrium to be poured into your eyes, and permit me to anoint them with balsam, that this ignorance may fall from your sight, and that you may behold truth as in a clear glass. But,” says Basil Valentine, after a long exhortation in this strain, “I will put an end to my discourse, lest my tears, which I can scarcely prevent continually falling from my eyes, should blot my writing, and, whilst I deplore the blindness of the world, blemish the lamentation which I would publish to all men.”

Such is the trash in which these authors abound, and in which curious facts and ingenious speculations are often enveloped.

Basil Valentine was succeeded by the more celebrated Paracelsus, a native of a village near Zurich in Switzerland.¹ In this remarkable person, all the follies and extravagance of the Alchemists were united;—he pretended to the discovery of the grand secret of the universal remedy: and his writings, which are very numerous, overflow with the whims and oddities of the sect; his zeal was more directed to the acquisition of popularity than to the advancement of science; his enthusiasm was ever misemployed; and he sought the elevation of his own character in the abuse and depretiation of his predecessors and contemporaries. He terminated a life, stained with every vice, and deficient in every virtue, in the year 1541, at an obscure inn at Saltzbourg, in Bavaria.

¹ He assumed the formidable title of Philippus Aureolus Theophrastus Bombastus Paracelsus ab Hohenheim.

“Hunc virum,” says Boerhaave, “alii coluerunt pro Deo, imo locutus sum cum hominibus qui credunt eum non esse mortuum, sed vivum sedere in sepulchro pertasum peccatorum et malorum hominum.” The following is an illustrative anecdote of his impudence: “Cum ascendere Cathedralam physico medicam, sumsit vas æneum cum igne, immisit sulphur et nitrum, et simul Galenum, Avicennam, et Arabes cecidit in ignem, dicens, sic vos ardeditis in gehennâ.”

In the history of medicine, Paracelsus deserves more honourable mention ; for he enriched the *Materia Medica* with many powerful remedies, derived from the mineral world, among which several preparations of mercury deserve especial notice ; nor was he unacquainted with the virtues of opium, and other powerful drugs of vegetable origin. These he administered with a daring but often successful hand, and gained such celebrity, that, in 1527, he was promoted by the magistracy of Basle to the office of Professor of Physic. In this he expounded his own doctrines, asserting that that which was denied him from above had been granted by the infernal deities ; and that to them he was indebted for those great secrets of physic and philosophy which he should divulge for the advantage and salvation of his hearers. Paracelsus, however, soon became weary of his situation, and terminated his professorial career, which was ill suited to his genius and inclinations, in the year 1528 ; he left Basle, and his subsequent life was one disgusting scene of dissolute irregularity.

The last person whose name deserves to remain upon the chemical records of the sixteenth century is Van Helmont of Brussels, born in 1577, ¹ who, at an early age, made considerable progress in philosophical studies. As a physician, he adopted the doctrines of the chemical school, and rejected those of Aristotle and Galen ; he effected cures so numerous and surprising, that he was accused by the inquisition of employing supernatural means, which induced him to retire into Holland. The writings of Van Helmont are chiefly upon medical subjects ; those connected with chemistry contain some curious speculations respecting aeriform fluids, which he calls *gases*, a term now in common use. He also speaks of a subtile invisible agent, called *Blas*, which, he says, is an ethereal emanation from the heavenly bodies. “ Winds are air agitated by the *Blas* of the stars.” ²

The doctrine of the Four Elements, as established by the ancient philosophers, underwent several alterations in the hands of the chemists of the sixteenth century. The former regarded Earth, Water, Air, and Fire, as the universal rudiments of all matter, and assigned to each its particular station in the universe. Earth tended towards the centre, water to the surface of the globe ; air occupied a middle station between water and fire, which last was considered as the most rare, subtile, and active of all things,

¹ The year 1558, given in Moreri, *Dictionnaire Hist.* is obviously incorrect, “ Anno 1591, qui erat mihi decimus septimus,” &c. (Van Helmont, *opera omnia*, 1707. *Studia Authoris*.)

² “ Nescivit inquam schola Galenica hactenus differentiam inter gas ventosum, quod mere aer est, id est ventus per alietum blas commotus, gas pingue, gas siccum, quod sublimatum dicitur, gas fuliginosum sive endemicum, et gas silvestre sive incoercibile, quod in corpus non cogi potest visibile.” (*Oper. om.* p. 599.)

it was supposed to constitute the heavenly bodies, and to confer life and action upon the other principles, to various combinations of which the different productions of nature were referred.

Basil Valentine, Paracelsus, and Van Helmont, speak of Salt, Sulphur, and Mercury, as the elementary principles of bodies; but the passages in their works referring to this hypothesis, are too dark and absurd to merit quotation; it was, however, adopted by several of their contemporaries and successors.

During the sixteenth century, some progress was made in the elucidation of the chemical arts, especially of Metallurgy, upon which subject the works of Agricola, and of Lazarus Erckern, merit particular notice. The former has detailed, at considerable length, the various operations employed in mining, and his descriptions are at once correct and elegant; but his attempts at theory are deeply tinged with the prevailing follies of the age. Agricola, who died at Chemnitz in 1555, was succeeded by Erckern, superintendent-general of the German mines; "he is an experienced, candid, and honest writer, relates nothing but what he had himself seen, without a word of theory or reasoning, and every where speaks as if he were sitting before the furnace and relating what passed."²

After wading through the thick fog of alchemical speculation, which envelopes the writers of this period, it is a relief to meet with one whose details are thus intelligible, and who adheres to matter of fact.

The periods we have now considered teemed with searchers for the philosopher's stone,—the elixir of life,—and the universal medicine. Of these such have hitherto only been noticed as conduced, by their experiments and discoveries, to the progress of chemical science.

The records of the fifteenth and sixteenth centuries present a motley group of these adventurers solely devoted to the occult art of transmutation. Some were open impostors; others deluded believers; but their respective histories are, in general, so similar,

¹ The mineralogical works of Agricola display very minute information upon the most important parts of his subject. They are, 1. *De ortu et causis subterraneorum*. 2. *De natura eorum quæ effluunt ex terrâ*. 3. *De natura Fossilium*. 5. *De medicatis fontibus*. 6. *De subterraneis animantibus*. 7. *De veteribus et novis metallis*. 8. *De re metallica*. This last has passed through several editions, and is an excellent compendium of what was then known upon the theory and practice of the miners art, and of the working of metals.

² "Liber ejus (Lazarus Erckern), in folio, est editus lingua Teutonica, pollicem crassus et iterum recusus est in Germana, in 4to. Est auctor in hac parte optimus." (Boerhaave.)

that an account of one will suffice:¹ Bernard Trevisan, who was born at Paris early in the fifteenth century, and who suffered severely under this intellectual epidemic, may be cited for the purpose. He commenced his career with the unsuccessful repetition of certain processes of transmutation described by Rhazes, in which he expended eight hundred crowns. The perusal of Geber's treatise on the perfection of the metals rekindled his hopes, and, after wasting two thousand crowns upon apparatus and materials, this experiment proved as fruitless as the former. The writings of Ruspescissa, Archelaus, and Sacrobosca, shortly afterwards engaged his notice; and, to ensure success, he associated himself with a monk, and performed a variety of silly but laborious experiments, at the expence of more than a thousand crowns. He submitted the same portion of spirit of wine to three hundred distillations, and was engaged during a period of twelve years, in a series of fruitless and unmeaning operations upon alum, common salt, and copperas. At length he quitted his native country for Italy; thence he proceeded to Spain and Turkey, in search of the adepts of the art, from whom he hoped to acquire the secret, and reimburse himself. Thus having squandered the scanty remains of his broken fortune, and reduced nearly to beggary, he retired to the isle of Rhodes, where he entered the service of Arnold of Villa Nova, from whom he states that he obtained that which he had so long searched for. So true is that definition of Alchemy, which describes it as an art without principle, which begins in falsehood, proceeds in labour, and ends in beggary.

Entering upon the seventeenth century, the historian of Experimental Science must ever pause to pay a tribute of gratitude and respect to the celebrated Francis Bacon; a man whose faults as a statesman have been eclipsed to the eyes of posterity, by the brilliancy and excellence of his philosophical character.

It may commonly be observed, that those who are gifted by nature with superior genius or uncommon capacity,—who are destined to reach the meridian of science,

¹ Among the English alchemists, we may enumerate George Ripley, who, in 1471, wrote the *Compound of Alchémie*, dedicated to Edward IV.; and the celebrated Elias Ashmole, who called himself *Mercuriophilus Anglicus*, and who published and edited many treatises on alchemy. He founded the Ashmolean Museum at Oxford in 1679. The reader who may wish to amuse himself with the nonsense of our own alchemists, is referred to the *Theatrum Chemicum Britannicum*, containing severall poetick pieces of our famous English philosophers who have written the *Hermétique mysteries* in their owne antient language. By Elias Ashmole, Esq. *Qui est Mercuriophilus Anglicus*, and to the celebrated alchemical work *Phlaelethes*.

The following act of parliament, which Lord Coke calls the shortest he ever met with, was passed in the fifth year of Henry IV.: "None from henceforth shall use to multiply gold or silver, or use the craft of multiplications, and if any the same do, he shall incur the pain of felony." (Watson's *Chemical Essays*.)

or to attain exalted stations in the learned professions, have exhibited early symptoms of future greatness: either indefatigable industry, or extraordinary sagacity, or ardent enthusiasm, have marked their entrance into the affairs of life. At the age of sixteen, Bacon was distinguished at Cambridge; and, very shortly afterwards, struck with the frivolous subtilty of the tenets of Aristotle, he appears to have turned his mind into that channel which led on to future eminence. The solid foundation of his scientific character is the *Instauration of the Sciences*. It opens with a general and philosophical survey of the subject; whence he proceeds to infer the futility of the ancient philosophical systems, and to point out Induction, from sober and severe experiments, as the only road to truth. Pursue this, he says, and we shall obtain new powers over nature; we shall perform works as much greater than were supposed practicable by natural magic, as the real actions of a Cæsar surpassed the fictitious ones of a hero of romance.

Speculative philosophy he likens to the lark, who brings no returns from his elevated flights; experimental philosophy to the falcon, who soars as high, and returns the possessor of his prey.

Illustrations of the new method of philosophizing, and the mode of arranging results, conclude this admirable and unrivalled performance.

To do justice to this work, we must, for a moment, forget the present healthy and vigorous constitution of science, and view it deformed and sickly in the reign of Elizabeth. We shall then not be surprised at the irrelative observations and credulous details which occasionally blemish this masterly production of the human mind.

But the history of Lord Bacon furnishes other materials for reflection. Upon the accession of James I., he became successively possessed of the highest honours of the law, and acquired great celebrity as a public speaker and a man of business; yet, amidst the harassing duties of his laborious avocations, he still found time to cultivate and adorn the paths of science, the pursuit of which furnished employment for his scanty leisure and relaxation in his professional toils; and, when ultimately disgraced, "his genius, yet unbroken, supported itself amidst involved circumstances and a depressed spirit, and shone out in literary productions." Nor should the munificence of his royal master remain unmentioned, who, after remitting his fine, and releasing him from his prison in the Tower, conferred upon him a large pension, and used every expedient to alleviate the burden of his age, and to blunt the poignancy of his sufferings.

After the death of Lord Bacon, which happened in April 1626, in the 66th year of his age, the records of science begin to assume a brighter aspect; and we discern true knowledge emerging from the dungeons of scholastic controversy, and shaking off the shackles of polemical learning.

The philosophers by fire, as the Chemists were emphatically termed, no longer exclusively engaged in seeking for the elixir of life, and the stone of transmutation, began to direct their endeavours towards more attainable and useful objects. They availed themselves of the accumulated facts collected by the misguided zeal and barren labours of their predecessors, and combined these useless and unseemly materials into the foundations of a beautiful and useful department of knowledge, but their progress was slow, and not unfrequently interrupted by relapse into the follies of Alchemy.

Glauber of Amsterdam,¹ and in this country the Honourable Robert Boyle, are characteristic writers of the middle of the seventeenth century. The former has detailed many curious and interesting facts respecting neutral salts, acids, and animal and vegetable substances; but his descriptions are darkened by the language of the adepts, and valuable truths are disguised by being blended with the unintelligible jargon of the black art.

The perusal of Glauber's chemical works leads to some surprise at the multitude of facts with which he was acquainted, and, among them, we meet with discoveries which have been considered of modern date. He particularly describes the production of vinegar during the destructive distillation of wood. (*Miraculum Mundi*, p. 1) The following may be selected from among many similar passages in his writings, as exhibiting the active and original turn of mind of this keen and curious inquirer, and as containing the germ of many truths which have been more fully developed in our own time.

"But what other things the said juice of wood is able to effect, we cannot here declare, by reason of our intended brevity; yet this I will add, that, if this acid spirit be rectified, it may be used in the preparation of good medicines; in mechanic arts; in the making of many fair colours from the extraction of metals, minerals, and stones; and for all things for which common vinegar is used; yea, far more commodiously, because it much exceedeth common wine and beer vinegar in sharpness."

He also mentions the tar produced in the same process, which he recommends as

¹ A collection of Glauber's works, in Latin, was published at Franckfort, in 1658, in 8vo, and in 1659 in 4to. An English translation was published at London, in 1689, by C. Pack.

efficacious in preserving wood that is exposed to weather, and speaks of it, when mixed with ashes, as a profitable and quickly acting manure. He further points out the method of concentrating the vinegar of wood by exposure to cold, which freezes the phlegm only, but the sharp spirit is not turned into ice, but remaineth in the middle of the hogshead, so sharp that it corodeth metals like aqua-fortis. If hop-poles be dipped in the oil, it not only preserves them, but fattens the plant; and as insects abhor these hot oils, if they be applied to the bark of fruit-trees, it will defend them from spiders, ants, canker-worms, and other insects; by this means also rats and mice may be prevented from creeping up hovel-posts, and devouring the grain." Glauber details a number of experiments relating to the action of this vinegar of wood, on limestone, and notices the uses of its compounds; and that he was accurately acquainted with its superior acidity, appears from the following quotation: "It is said that Hannibal made a passage through the Alps for himself and his army, softening the rocks by the benefit of vinegar. What vinegar that was, histories do not mention. Perhaps it was the vinegar of wine; but if he had had the vinegar of wood, he might sooner have attained his desire."

These shrewd remarks and useful observations are thickly scattered through the verbose pages of Glauber. He enriched the laboratory with new agents, and into medicine he introduced several new and useful remedies. Upon the arts he bestowed many improvements, and was among the first who seriously endeavoured to benefit agriculture by the medium of experimental chemistry.

Boyle has left voluminous proofs of his attachment to scientific pursuits, but his experiments are too miscellaneous and desultory to have afforded either brilliant or useful results; his reasoning is seldom satisfactory; and a broad vein of prolixity traverses his philosophical works. He was too fond of mechanical philosophy to shine in Chemistry, and gave too much time and attention to theological and metaphysical controversy to attain any excellence in either of the former studies. He who would do justice to Boyle's scientific character, must find it rather upon the indirect benefits which he conferred, than upon any immediate aid which he lent to science. He exhibited a variety of experiments in public, which kindled the zeal of others more capa-

¹ Boyle was born in January 1627, at Lismore, in the Province of Munster, in Ireland. He was educated at Eton, and afterwards travelled in Italy, Switzerland, and France, and returned to England in 1644. In 1668 he took up his residence in London; and in 1680 was elected President of the Royal Society. He died on the 30th of December 1691, aged 65.

ble than himself. He was always open to conviction; and courted opposition and controversy, upon the principle that truth is often elicited by the conflict of opinions. His disposition was amiable, mild, and generous, and he was at once the patron of learning and of virtue.

The merit of bringing Hooke¹ before the public, and of pointing out to him the road to eminence, is chiefly due to Mr Boyle, who, in the troublesome and bigotted periods of the commonwealth and protectorship, associated himself with a few philosophical friends at Oxford, for the purpose of promoting experimental inquiry. Hooke, who enjoyed the advantage of having been educated at Westminster school, under Dr Busby, was introduced in the year 1655 to this select society, where his original and inventive genius was soon discerned and called into action. Boyle engaged him as his operator and assistant, and his talents were turned, with great success, to the invention and improvement of philosophical instruments, and to many important subjects connected with the mechanical arts.

It was about this period that the physical properties of the atmosphere began to attract notice, and that the favourite scholastic notion of Nature's abhorrence of a vacuum was called into question. Galileo was perhaps the first who broke this spell of Aristotelian philosophy; and in the year 1644, the grand discovery of atmospheric pressure, and its variation, was announced by Torricelli, the celebrated inventor of the barometer.² The idea of constructing a machine for the purpose of rarefying air, first

¹ Sir Godfrey Copley, in a letter written about the time of Hooke's death, says, "Dr Hooke is very crazy; much concerned for fear he should outlive his estate. He hath starved one old woman already, and, I believe, he will endanger himself to save sixpence for any thing he wants." In another, written a few weeks after his death, Sir Godfrey says, "I wonder old Dr Hooke did not choose rather to leave his L. 12,000 to continue what he had promoted and studied all the days of his life,—I mean mathematical experiments, than to have it go to those whom he never saw or cared for. It is rare that virtuosos die rich, and it is pity they should, if they were like him." (*Dr Ducarrel's MSS.* quoted in *Biog. Dict.*) Hooke sometimes declared, that he intended to dispose of his estate for the advancement of natural knowledge, and to promote the ends for which the Royal Society was instituted; to build a handsome edifice for the Society's use, with a library, laboratory, and repository, and to endow a professorship. (*Life by Waller.*)

² The Peripatetics maintained, that the creation of a vacuum was impossible, even to supernatural power. This dogma was first shaken by a circumstance which happened to some workmen employed by the Grand Duke of Tuscany. Having sunk a deep well, they endeavoured to bring the water to the surface by a common sucking-pump, but found, to their surprise, that they could only make it ascend to the height of about 30 feet. Galileo, whose talents had gained him great celebrity and respect, was consulted in this emergency. His answer was, that, although nature does dislike a vacuum, there is a certain limit to her antipathy, equivalent to the pressure of a column of water eighteen palms high.

occurred to Otto Guericke, who, after many fruitless attempts, succeeded by means of a sucking pump, in withdrawing a considerable portion of air from the interior of a copper ball. With this awkward and imperfect air-pump, he performed several notable experiments. One of these is often exhibited at the present day. It consists in exhauſting a hollow brass globe, composed of two hemiſpheres, cloſely fitted to each other. When a portion of the interior air is removed, the preſſure of the exterior atmosphere is ſuch as to reſiſt conſiderable force applied to ſeparate the hemiſpheres. This is called the Magdeburgh experiment, and was firſt publicly exhibited in the year 1654 before the deputies of the empire, and foreign miniſters aſſembled at the diet of Ratiſbon. This original air-pump, invented by the Burgo-maſter of Magdeburgh, was greatly improved by Hooke, who, in conjunction with Boyle, performed by its means a variety of new and important experiments, illuſtrative of the mechanical properties of the atmosphere, which, at a ſubſequent period, tended conſiderably to the progreſs of pneumatic chemistry.

The works of Hooke, chiefly intereſting to the chemiſt, are his *Micrographia* and *Lampas*, the former published in 1664, the latter in 1677. They contain anticipations of many of the ſubſequent changes and improvements of chemical theory, which will be noticed in a future page of this hiſtory.

Both the private and public character of Dr Hooke exhibit many faults, and are ſtained with many blemiſhes. His temper was peeviſh, reſerved, and miſtruſtful; and he wanted that candour and dignity of mind which ſhould raiſe the philoſopher above the level of ordinary men. He was born at Freſhwater, in the Iſle of Wight, in 1635, and died in London in the year 1702.

Immediately after the Reſtoration, the gentlemen who formed the Philoſophical Society at Oxford adjourned to London, where they held their meetings in Greſham College, and conſiderably extended the number of their members. The King, who himſelf loved ſcience, countenanced and patroniſed their proceedings; and, on the 15th of July 1662, granted a royal charter, conſtituting them a body corporate, under the name of *The Royal Society of London, for promoting Natural Knowledge*. In the year 1665 was published the firſt number of the *Philoſophical Transactions*, of which work, juſtly regarded as the ſtandard of Engliſh ſcience, a volume has been published annually ſince the year 1762.

This laudable and rare example of Charles the Second was followed by Lewis the Fourteenth of France; and in the year 1666 the *Royal Academy of Sciences* was inſtituted at Paris, under the immediate protection of that monarch. Neither was the

patronage cold, nor the honours empty, which were bestowed by Lewis on the followers of science. Salaries he conferred upon scientific bodies, and pensions upon learned men, "a generosity," says Hume, "which does great honour to his memory, and in the eyes of all the ingenious part of mankind will be esteemed an atonement for many of the errors of his reign. We may be surprised," continues the historian, "that this example should not be more followed by Princes, since it is certain that bounty so extensive, so beneficial, and so much celebrated, cost not this monarch so great a sum as is often conferred upon one useless overgrown favourite or courtier." Happily for the scientific character of Britain, the genius, talents, and exertions of individuals have ever been sufficient to counterbalance such advantages; and thus nurtured and protected, the growth of science has not been less rapid or vigorous than where she has enjoyed the sunshine of royal favour.

With the great and unrivalled name of Newton, we close the records of the seventeenth century. To him Chemistry is indebted for the first correct views respecting the nature of combination; a subject which had little engaged the attention of the more sensible experimentalists of the preceding periods, and which was formerly attributed to the occult qualities of the Aristotelians, and afterwards to the mechanical forms of the particles of bodies.¹

Chemical affinity was referred by Newton to the different attractive powers of the different kinds of matter in regard to each other. Salt of tartar becomes moist by exposure to air, because that salt attracts the humidity of the atmosphere. Muriatic acid unites with salt of tartar by virtue of their respective attractions; but when oil of vitriol is poured upon this compound, the former acid is displaced by the superior attraction of the latter. Silver dissolved in aqua-fortis is separated from that menstruum by the superior attraction of quicksilver; in like manner copper separates quicksilver; and iron, copper. Referring to these and other similar instances, "does not this" says he "argue, that the acid particles of the aqua-fortis are attracted more strongly by iron than by copper, by copper than by quicksilver, and by quicksilver than by silver?" Such are the simple but clear, and, in most instances, correct suggestions relating to the subject of attraction, which Chemistry owes to the great luminary of Mechanical Philosophy.

In tracing the history of Chemistry from early times, through the dark ages, to the

¹ We shall again have occasion to refer to certain chemical opinions of Newton. In the present instance, reference is made to the thirty-first query annexed to the *Third Book of Optics*. (Newton, *Opera Omnia*, 4to, Lond. 1782.)

beginning of the last century, I have only noticed such authors as conducted by the weight or novelty of their writings, the importance of their discoveries, or the example of their zeal, to the more immediate progress and elucidation of this department of philosophy. The annals of a period so extensive must necessarily record a host of experimentalists, to whose researches it would upon the one hand be impossible to do justice; and whose names, on the other, it would be useless to repeat. It may however be remarked, that alembics, and other complex distillatory apparatus, were employed by the alchemical physicians who flourished between the ninth and thirteenth centuries. Mesue mentions the distillation of rose-water, and the production of spirit of wine is noticed by Raymond Lully. At this time, too, furnaces of peculiar construction, and a variety of complex apparatus and accoutrements, were introduced into the laboratory.

During the fifteenth and sixteenth centuries, Alchemy was at its acmé, and many were the unwary and avaricious who were entrapped by the golden prospects and plausible mysticism of the art. Among these was that admirable artist Mazzuoli of Parma, better known under the name of Parmagiano.

Curious discoveries and useful inventions multiplied rapidly during the seventeenth century. Kunckel, in Saxony, successfully promoted the Chemistry of the Arts. In 1669, Brandt of Berlin discovered Phosphorus, and about the same time Homberg accidentally produced a spontaneously inflammable compound, which he called Pyrophorus. In 1674 the elder Lemery acquired great and deserved fame at Paris as a chemical lecturer. He was the first who threw aside the affected and pompous diction habitually indulged in by his predecessors and contemporaries, and adopted a simple and perspicuous style, which at once tended to the ready diffusion of his subject, and to its permanent popularity. When he published his course, "it sold" says Fontenelle "like a novel or a satire."

The establishment of literary and scientific societies during this age was another grand step towards the promotion of knowledge, and the period was particularly propitious to their progress. Bacon, Galileo, and Kepler, had opened that road to truth which was so eagerly and successfully pursued by Boyle, Hooke, and Mayow, in this country, and in which the miraculous mind of Newton displayed its brilliant powers. In Germany, Beccher and Stahl are entitled to particular mention. The suggestions of the former, who was a man of an acute and inquisitive turn of mind, led the latter into that train of speculation which terminated in producing the Phlogistic Theory, and which will presently be more particularly considered. Homberg, Geoffroy, and

the two Lemerys, were zealous followers of experimental chemistry in France, at the establishment of the Royal Academy of Sciences. In short, the independent zeal and healthy activity in scientific pursuit, which has since marked its progress in Europe, became manifest early in the seventeenth century; and the causes I have attempted to unfold contributed to the splendour which it began to acquire about the end of that important era in the general history of the world. The clouds of ignorance and error quickly dispersed before this happy dawn of true knowledge; and science, no longer enveloped in scholastic mystery and absurd speculation, began to display those inherent charms, which gained her the courtship and admiration of every liberal and cultivated mind, and which laid the foundation of that extended dominion which she acquired in the succeeding age.¹

SECTION II.

STATE OF CHEMISTRY AT THE OPENING OF THE EIGHTEENTH CENTURY.—OPINIONS OF BECCHER AND STAHL RESPECTING THE PHENOMENA OF COMBUSTION, COMPARED WITH THE VIEWS OF REY AND MAYOW.—PNEUMATIC CHEMISTRY OF HAILES AND BOERHAAVE.—INVENTION OF THE THERMOMETER.

THE history of the progress of Chemistry during the seventeenth century presents many active and able inquirers, whose researches tended to develop new properties and combinations of bodies; but their attempts at theory and generalization were, with few exceptions, absurd and abortive. They consisted in wild hypothesis and vague speculation, and were founded, not upon the sober and steady basis of truth, but upon the unreal and tottering visions of the imagination. The spirit of Lord Bacon was slow in animating experimental philosophy, until Newton rose to surprise and illumine the world. It then assumed a new and cheerful aspect, and quick was its growth, and illustrious its progress, under the invigorating influence of that sun of science.

Although Chemistry does not lie under the same weighty obligations to Newton as

¹ Those who are desirous of consulting the alchemical authors, and of becoming particularly acquainted with the titles of their voluminous productions, will find a curious body of information on these subjects in the *Histoire de la Philosophie Hermetique*, Paris, 1742.—Gobet's *Anciens Mineralogistes*, published at Paris in 1779, gives some details of the early progress of Mineralogical Chemistry in France.

mechanical philosophy, he conferred upon it a great and lasting benefit, by the disclosure of those clear and simple views which have already been alluded to.¹ The important deductions, too, which flow in easy perspicuity from his experimental researches, soon became general models of imitation; and the new style which we discern in the philosophical authors of the early part of the eighteenth century throughout Europe, may, in a great measure, be referred to the lofty example before us.

No sooner was the spell of Alchemy broken, than the phenomena of combustion began to attract the notice of the early chemical theorists. The influence of the air upon this process had been long observed, and many of the changes suffered by the com-

¹ The following passages, in addition to the previous observations in the text, will be sufficient in illustration of Newton's views of *Elective Attractions*.

“Have not the small particles of bodies certain powers, virtues, or forces, by which they act at a distance, not only upon the rays of light, for reflecting, refracting, and reflecting them, but also upon one another, for producing a great part of the phenomena of nature? for, it is well known, that bodies act one upon another by the attractions of gravity, magnetism, and electricity; and these instances show the tenor and course of nature, and make it not improbable that there may be more attractive powers than these. For nature is very consonant and conformable to herself. How these attractions may be performed I do not here consider; what I call attraction may be performed by impulse, or by some other means unknown to me. I use that word here to signify only, in general, any force by which bodies tend towards one another, whatsoever be the cause. For we must learn from the phenomena of nature what bodies attract one another, and what are the laws and properties of the attraction, before we inquire the cause by which the attraction is performed. The attraction of gravity, magnetism, and electricity, reach to very sensible distances, and so have been observed by vulgar eyes, and there may be others which reach to so small distances as hitherto escape observation, and perhaps electrical attraction may reach to such small distances even without being excited by friction. For, when salt of tartar runs *per deliquium*, is not this done by an attraction between the particles of the salt of tartar and the particles of the water which float in the air in the form of vapours? And why does not common salt, or saltpetre, or vitriol, run *per deliquium*, but for want of such an attraction? Or why does not salt of tartar draw more water out of the air than in a certain proportion to its quantity, but for want of an attractive force after it is satiated with water? And whence is it but from this attractive power that water, which alone distils with a gentle and lukewarm heat, will not distil from salt of tartar, without a great heat? And is it not from the like attractive power, between the particles of oil of vitriol and the particles of water, that oil of vitriol draws to it a good quantity of water out of the air; and after it is satiated, draws no more, and in distillation lets go the water very difficultly? And when the water and oil of vitriol, poured successively into the same vessel, grow very hot in the mixing, does not this argue a great motion in the parts of the liquors? And does not this motion argue that the parts of the two liquors, in mixing, coalesce with violence, and, by consequence, rush towards one another with an accelerated motion? And when *aqua-fortis*, or spirit of vitriol, poured upon filings of iron, dissolves the filings with a great heat and ebullition, is not this heat and ebullition effected by a violent motion of the parts?” &c. “When spirit of vitriol, poured upon common salt or saltpetre, makes an ebullition with the salt, and unites with it, and, in distillation, the spirit of the common salt or saltpetre comes over much easier than it would do before, and the acid part of the spirit of vitriol stays behind;—does not this argue that the fixed alcaly of the salt attracts the acid spirit of the vitriol, more strongly than its own spirit; and, not being able to hold them both, lets go its own?”—Newton's *Optics*, Opera omnia, 4to, Lond. 1782.

bustible had been examined with a surprising degree of acuteness and precision; for fire was almost the only agent employed at that period to effect combination and decomposition. These inquiries constitute a prominent feature in the history of Chemistry. It may therefore be requisite to pursue them with a minute attention, which may at first appear tedious, but which will gain in importance and interest as they proceed.

The first speculations in theoretical Chemistry deserving attention, are those of John Joachim Becher of Spire, who died in England in 1685. He gained considerable celebrity at Vienna and Haerlem, for improvements in arts and manufactures, but was induced to retire to this country, in consequence of the jealousy of rivals, and the neglect of those upon whom he had conferred benefits. His works abound in shrewd and witty remarks, and in deep and curious reasoning,—in frivolous subtilty, and in weighty and sensible observations. His hypothesis respecting the origin of the varieties of matter, from the mutual agencies and combinations of a few elementary principles, though unnecessarily blended with scriptural history, are characterized by considerable brilliancy of thought and originality of invention. They are detailed at great length in his *Physica Subterranea*, which treats on the original creation of matter, and the transition and interchange of elements. The *Institutiones Chemicæ*, or *Œdipus Chemicus*, of this author, is another curious production, containing the history of the chemical elements, and describing the leading operations of the laboratory. Earth was the favourite element of this philosopher, of which he supposed three varieties to exist, namely, a vitrifiable, a metallic, and an inflammable earth. Of these the various productions of nature were formed. ¹

¹ Becher wrote voluminously upon a great variety of subjects. His principal chemical works are as follows.

1. *Œdipus Chemicus*. 2. *Metallurgia, de generatione, refinatione, et perfectione Metallorum*. 3. *Physica Subterranea*, and its various appendices. 4. *Parnassus Medicinalis Illustratus*. 5. *Laboratorium Portatile*. 6. *Chymischer Rosen-garten*.

Becher's *Œdipus* is dedicated to Francis Sylvius Deleboe, who, in 1658, was elected the first Professor of Medicine in the University of Leyden. He was a man of an acute mind, as appears from his various essays and tracts, more especially from his *Prælex Med. Idea Nova*. He died at Leyden in 1672. "Utilissimum profecto munus subisti, quò tui auditores non verba sed corpora, non chymerasticos terminos, verum ipsas reales enchyrisas, non inanes denique et immateriales facultates, sed a te demonstrati, effectus causas practicas audiunt, vident, tangunt." Becher everywhere compliments him as a man not of words, but of deeds; as a philosopher, who eminently sought to render science popular and intelligible to all capacities.

The language of Becher's *Physica Subterranea* is sufficiently inelegant and incorrect. "Lxcuso Latini-

But the most celebrated chemical theorist of the latter part of the seventeenth century is Ernest Stahl, born at Alispach in Franconia, in 1660. He adopted many of the opinions of Beccher respecting the cause of inflammability, and upon these foundations reared the celebrated System of Phlogiston, according to which, inflammability is supposed to depend upon the presence of a highly subtile and elastic matter, which, at certain temperatures, is thrown into violent motion, and appears under the form of flame or fire. Combustion is the separation of this principle, and bodies contain it in various proportions. Charcoal, for instance, when burned, leaves scarcely any residuum, and is, therefore, nearly pure phlogiston. Antimony, when burned, affords a large proportion of earthy matter. If this earth be heated with charcoal, or other matter abounding in phlogiston, antimony is regenerated; this metal, therefore, is a compound of earth and phlogiston.

If sulphuric acid, which is not inflammable, be distilled with oil of turpentine, which is extremely so; or, in other words, if phlogiston be added to sulphuric acid, sulphur is obtained. Sulphur, therefore, is a compound body, consisting of sulphuric acid and phlogiston. If sulphur and common potash be fused together, a brown compound is obtained, formerly called liver of sulphur, and the same product results when charcoal is heated with Glauber's salt, which consists of soda combined with sulphuric acid. Such was Stahl's explanation of the phenomena of combustion, and such the apparently plausible experimental proofs upon which it was founded.¹

In Germany and in France, the phlogistic doctrine was received with that thoughtless and eager enthusiasm which suffers the blaze of novelty to eclipse the steady light of truth, and which is rather captivated by plausible exterior than by internal excellence. Even in this country the experiments of Boyle and of Hooke, if not forgotten, were over-

tatem in hoc opere," says he, "*quam barbaram esse fateor, ob materiem et ob descriptionem, in specie descriptionis modum: ex ore enim dictantis totum opus conceptum est. Sic rebus attentus, verba neglexi.*" This is at once an example and apology.

¹ Stahl's doctrines are very ably set forth in his *Three Hundred Experiments*, published at Berlin in 1731, and in his *Fundamenta Chemicæ*, Nuremberg, 1723 and 1732. He observed the necessity of air to combustion, and considered flame or fire as resulting from its violent ethereal agitations. Stahl is continually urging circumspection in hypotheses, yet preconceived opinions are always leading him to erroneous conclusions, as the following passages amply prove. "*Aer ignis est anima, hinc, sine aëre nihil potest accendi, vel inflammar.*"—"Aer in motum excitatus, seu ventus artificialis, vel etiam naturalis, mirum excitat motum æthereis, seu flammam, hinc ad ignem fusorium, et vitrificatorium, promovendum, foliis opus est, imo gradus et vehementia ignis dependet multum ex aëre admissum." *Fund. Chem. dogmat. et ration.*

looked, and hypothesis for a time gained the ascendancy over facts; for it had been most satisfactorily demonstrated by those experimentalists, that bodies will not burn if air be excluded, and that, during combustion, a portion of the air is consumed by the burning body. Even at an earlier period, the same observation had been most pointedly dwelt upon and another equally important circumstance ascertained, namely, the increase of weight sustained by metals during their calcination. As early as 1629, Brun, an Apothecary, resident in the town of Bergerac in France, melted two pounds six ounces of tin, and in six hours the whole was converted into a calx, which weighed seven ounces more than the tin employed. Brun, surprised at this circumstance, communicated it to John Rey,¹ a physician of Perigord, who, in 1630, published a Tract upon the subject, in which he refers the increase of weight to the absorption and solidification of air: "Thus," says Rey, in the fanciful language of the period, "have I succeeded in liberating this surprising truth from the dark dungeons of obscurity; which was vainly but laboriously sought after by Cardan, Scaliger, Taschnus, Cæsalpinus, and Libavius. Others may search for it, but in vain, unless they pursue the royal road which I have cleared. The labour has been mine,—the profit is the reader's,—the glory is from above."

But amongst the authors whose researches tended to conclusions diametrically opposite to those of Stahl and his associates, and whose writings abound in anticipations of modern discoveries, no one stands so conspicuous as our countryman John Mayow.² His tracts, published at Oxford in 1674, relating to chemical, physiological, and medical subjects, abound in traits of original and inventive genius, and furnish the prototype of many discoveries, which have conferred great and lasting renown upon succeeding labourers in the field of Chemistry. It is the treatise upon nitre and the nitro-aerial spirit to which I principally allude, and of which it may be proper to give a short but connected sketch.

¹ *Essays de Jean Rey, Docteur en Medecine, sur la Recherche de la Cause pour laquelle l'Etain et le Plomb, augmentent de poids quand on les calcine.* Paris, 1777.

Of these curious essays, originally printed in 1630, a copy was discovered in the Royal Library at Paris in 1776. The scarcity of the first edition is in some measure accounted for in the "Advertisement" to the present, but the rarity of this reprint is very enigmatical.

² Mayow was born in Cornwall in 1645, and died in London in 1679, at the early age of thirty-nine. Dr Beddoes and Dr Yeats have asserted Mayow's claims to several modern discoveries; and in many other instances than those quoted in the text, he has certainly anticipated both the discoveries and inventions of some of his chemical successors. All Mayow's tracts are deserving of attentive perusal, and are of full knowledge. The first and second, *De Sal-nitro et Spirito Nitro-aërio* and *De Respiratione*, contain a vast body of chemical facts, resulting from well conceived and conducted experiments.

The atmosphere, he observes, contains a certain nitro-saline matter, a spirit, vital, igneous, and fermentative, which exists in, and may be obtained from nitre; that it supports combustion, but is itself incombustible; that it exists in nitric acid; that when antimony is exposed to the joint operation of heat and air, it imbibes the nitro-aerial particles, whence its increase in weight; and that a similar change may be effected by nitre or by nitric acid; that acidity depends upon the absorption of the same principle which in sulphuric acid is combined with sulphur, either during combustion, or during the exposure of pyrites to air: that fermentation is referable to a very similar cause: that it is necessary to vegetation, and present in all cases of combustion; that it is absorbed by animals during respiration; and that the same substance which contributes to the support of flame, is likewise required for the support of life. Mayow also was acquainted with the evolution of air during the action of nitric and vitriolic acids upon iron, and points out a mode of collecting it, in bottles inverted in vessels of the dilute acids. He observes that the air generated in these experiments, although expansible by heat, is probably different from the atmosphere, as is also the air which an animal has breathed, and in which a candle has burned.

These are a few of the important facts dwelt upon by Mayow, respecting the nature of the atmosphere, and of the cause of combustion. That they were not at the time opposed to the purely speculative notions of Stahl is truly remarkable, for they explain, in conjunction with the observations of Rey and others, the great obstacle to the phlogistic hypothesis, the increase of weight in the burning body; they show the real cause of the necessity of the presence of air, which, if combustion consisted in the mere evolution of the subtle principle of fire, could not be required; and they adduced experimental evidence, where Stahl merely surmised.

Another active inquirer occurs in this page of chemical history; one whose researches cleared the way for the great discoveries of the succeeding era, and to whom the merit is justly due of having opened a mine in the field of nature; who indulged, not in the speculative and metaphysical frivolities which characterize the productions of most of his predecessors, and many of his contemporaries, but followed nature with a steady and unerring step, and recorded his observations in a concise, unadorned and unaffected style. This was the Reverend Dr Stephen Hales.¹ He was the first

¹ Born in 1677, died in 1761. Dr Hales is one of the few divines who have employed their abundant leisure in philosophical and experimental researches. It is said that he received high preferment upon more

who instituted researches into the physiology of vegetation, a subject which he pursued with considerable ardour and perseverance. He also made a variety of experiments upon the extrication of air during the exposure of animal, vegetable, and mineral substances to heat. In perusing his *Essays* on these subjects, we frequently find him upon the verge of those splendid discoveries which fell to the lot of his fellow-labourers and successors; but the erroneous nature of his preconceived opinions induced him to take for granted that which experiment should have determined, and to rest satisfied with results which, had they been followed up, would inevitably have led to the most important and novel facts. His experiments do credit to his industry, but his conclusions betray feebleness of judgment. If, instead of regarding the various gaseous products obtained from the substances he operated upon, as consisting of common air contaminated by their effluvia, he had submitted them to more close investigation, he would doubtless have run a more brilliant and successful career. He is justly regarded as the founder of Pneumatic Chemistry, but he contributed few materials to the superstructure.

Herman Boerhaave,¹ of Leyden, who was a contemporary of Hales, pursued a

than one occasion, in order that he might attend to his humble parochial duties and continue his scientific pursuits.

He directed his attention to the quantity of moisture imbibed and emitted by different plants, and to the circulation of the sap, which, he says, put him upon making a more particular inquiry into the nature of a fluid which is so absolutely necessary for the support of the life and growth of animals and vegetables.

His *Specimen of an Attempt to analyse the Air by Chymiostatical Experiments* displays extraordinary ingenuity in the contrivance of experiments and apparatus. It was his misfortune to consider the various gases which he procured as mere modifications of atmospheric air. *Philos. Trans. Statical Essays*, London, 1731.

¹ Boerhaave was born in December 1668, at a village near Leyden. He died in September 1738. He was an eminent ornament of medicine, as well as of chemical science. His oration upon resigning the office of Governor of the University of Leyden has been justly eulogised by Johnson. (*Life of Boerhaave*.) He here declares in the strongest terms (says his eloquent biographer) in favour of experimental knowledge, and reflects with just severity upon those arrogant philosophers, who are too easily disgusted with the slow methods of obtaining true notions by frequent experiments, and who, possessed with too high an opinion of their own abilities, rather choose to consult their own imaginations than inquire into nature, and are better pleased with the charming amusement of forming hypotheses than the toilsome drudgery of making observations.

The emptiness and uncertainty of all those systems, whether venerable for their antiquity, or agreeable for their novelty, he has evidently shown; and not only declared, but proved, that we are entirely ignorant of the principles of things, and that all the knowledge we have is of such qualities alone as are discoverable by experience, or such as may be deduced from them by mathematical demonstration.

Boerhaave's contributions to physic were large and valuable. His principal chemical work is the *Elementa Chemicæ*, of which a good translation, with notes, was edited in 1753 by Dr Shaw. This work he

similar train of inquiries ; but, although many of his experiments were new and well conceived, he was not more happy in his conclusions, nor more fortunate in his discoveries. He attributed the elasticity of air to its union with fire, and considered its ponderable matter as susceptible of chemical combinations ; but the existence of different aeriform fluids escaped his notice.

The philosophers whose names have been now recorded, not only greatly added to the stock of chemical facts collected by their predecessors, but conferred new life and vigour upon the science by their occasional incursions into the regions of theory and rational speculation :—in this light, the works of Rey, Mayow, and Stahl, deserve particular attention ; the two former for correctness and precision, the latter for boldness and ingenuity.

About this period the Thermometer was brought to perfection, which tended materially to the progress of that most refined and difficult branch of Chemical Philosophy, relating to the nature and effects of heat. The researches, on this subject, will presently form an important feature in our history, which renders it proper to notice this instrument of such consequence in their prosecution.

That bodies change in bulk, with variations of temperature, must have been noticed at a very early period ; but there can be little doubt, that the idea of constructing an instrument for measuring these variations first occurred to Santorio,¹ Professor of Medicine, in the University of Padua, in the beginning of the seventeenth century ; he is also celebrated for his Medico-statical experiments, which are well burlesqued in one of the early numbers of the *Spectator*.²

dedicated to his brother, who was intended for the medical profession, but went into the church ; while Boerhaave, who originally studied divinity, relinquished it for physic and chemistry. Alluding to this circumstance, " Providence," says he, " has changed our views, and consigned you to religious duties, while I, whose talents were unequal to higher objects, am humbly content with the profession of physic."

In the *Elementa*, and in several of his Orations, are admirable remarks upon the useful application of Chemistry to other branches of knowledge. His observations upon its usefulness and necessity to the medical practitioner, may be well enforced at the present day ; for, excepting in the Schools of London and Edinburgh, Chemistry, as a branch of education, is either entirely neglected, or, what is perhaps worse, superficially and imperfectly taught. This is especially the case at the English Universities, and the London Pharmacopœia is a record of the want of chemical knowledge, where it is most imperiously required.

¹ Santorio was born in 1561 at Capo d'Istria, on the borders of the Gulf of Trieste. He died at Venice in 1636. His *Ars de Statica Medicina* was published at Venice in 1614. Much merit is due to the steady perseverance with which he opposed the occult remedies of the empirics of his day.

² No. 25. By Addison.

Santorio's thermometer consisted of a tube, blown at one end into a bulb, and with the other open extremity immersed into water. In cold weather the confined air contracted and the water rose in the tube—in a warm atmosphere the air expanded and the fluid fell. Santorio observed some other particulars connected with the operation of this thermometer, among which the increased influence of the sun's rays, when the bulb was blackened, deserves notice.

The Academicians del Cimento, whose early labours have already been mentioned, materially altered and improved the thermometer, by employing a liquid to measure temperature, instead of air, the changes of bulk in which, in a moderate range of temperature, are so considerable as to render the instrument extremely bulky and otherwise inconvenient. They generally used spirit of wine, and fixed a scale of degrees to the tube, with a view to ascertain its variations in bulk with greater precision. These instruments soon acquired considerable celebrity, and were largely circulated under the appellation of the Florence Glass. In this state the uses of the thermometer were extremely limited, no two instruments corresponded, and there being a free communication between the fluid and the external air, it was liable to evaporation,—yet was this thermometer much preferable to the over-sensible and bulky instrument of Santorio. There was another objection to spirit of wine, arising out of the readiness with which it assumes an elastic state, and which renders it unfit for measuring temperatures even below the heat of boiling water. Sir Isaac Newton, therefore, suggested the use of linseed oil, which, however, is extremely ill adapted to the purpose on account of its unctuousity, and the ease with which it solidifies. Quicksilver was first recommended by Roemer,¹ the eminent Danish philosopher, who discovered the motion of light; it was also employed by Dr Halley, and is now generally used. The advantages of this fluid metal in the construction of the thermometer are manifold; it retains its liquid state at very high and very low temperatures, and has the peculiar excellence of expanding very equally for equal increments of heat, which is far from the case with spirit of wine.

But the great improver of the thermometer was Fahrenheit,² a merchant of Dantzic, who, having failed in business, and being attached to chemical and mechanical pursuits, was obliged to gain a livelihood by making and selling these instruments. Fahrenheit used both spirit of wine and quicksilver, and hermetically sealed the tube containing the fluid; he also greatly improved the method of graduation, by establishing

¹ Born at Arhusen in Jutland, in 1644,—died at Copenhagen in 1710.

² Born at Dantzic in 1686,—died in 1724.

two points as the extremes of his scale, and subdividing the intermediate portion into a given number of degrees.

The division of the thermometric scale had occupied the attention of several learned and ingenious men; but it was Fahrenheit who pointed out the most accurate means of accomplishing this purpose. The curious circumstance of the water running from melted snow being always of the same temperature, appears first to have occurred to G \ddot{u} ricke of Magdeburgh, but was first applied to the graduation of thermometers by Sir Isaac Newton. Dr Hooke had observed that the quicksilver in the tube of the thermometer, plunged into boiling-water, always rose to the same height; accordingly, if a mercurial thermometer be put into melting snow, and the point at which the fluid stands, marked upon the tube, and then transferred to boiling-water, and that point also marked, and if the intermediate space be subdivided into any number of equal degrees, 100 for instance, it follows that, provided proper precautions have been taken in selecting and filling the tube, every thermometer so constructed will indicate the same degree, when applied to bodies of the same temperature. With regard to the boiling point, Fahrenheit observed it to differ under different degrees of atmospheric pressure, and pointed out the necessity of fixing it at a mean barometrical altitude. He had also noticed, that a degree of cold much more intense than that of ice might be procured by a mixture of snow and salt; and conceiving this to be extreme cold, he commenced his scale from that point, which is 32° below the freezing of water. Accordingly, Fahrenheit's scale commences at 0° , the temperature of his freezing mixture; the freezing point of water is marked 32° , and the boiling point 212° ; the space between the freezing and boiling of water being divided into 180° . The graduation of thermometers received its greatest improvement in 1742, by Celsius of Sweden, who commenced the scale at the freezing of water, and divided the space between it and the boiling point into 100° . This is the centigrade scale, now used in France. Reaumur's scale, in which the point of congelation is marked 0° , and that of boiling-water 80° , is used in some parts of the European Continent; and in Russia the descending scale of Delisle is sometimes employed, in which the boiling point of water is 0° , the freezing 150° . These scales have each their merits and defects. In the event of innovation, the interval between the freezing and boiling of mercury, might be divided into 1000 equal parts; the former being 40° below 0° of Fahrenheit, the latter about $+ 670^{\circ}$. The degrees would thus be sufficiently small to be expressed without fractions; and the commencement of the scale,

which is about the lowest natural temperature, would be so low, as to preclude the frequent necessity of expressing negative degrees.¹

From this sketch of the history of the thermometer, it is obvious, that its operation depends upon the circumstance of fluids diminishing in bulk by diminution of temperature, and the contrary; which is really the case with all fluids except water. This important fact was observed by the Florentine Academicians in their early experiments, and it is among the most curious and interesting discoveries of that zealous and active association of experimentalists. Having filled a large thermometer tube with water, they plunged it into a mixture of salt and snow. The water presently began to contract in bulk, and descend in the tube; but, instead of continuing to do so, till it reached the freezing point, after a short time it commenced expanding; the expansion went on till a portion of the water froze, and was then very suddenly increased.

The temperature at which water thus begins to expand by cooling is 40° Fahrenheit, and water cooled down to 32°, that is, 8° below 40°, occupies the same space as

¹ This proposal is suggested by Mr Murray. *System of Chemistry*, Vol. I.

² The following unaffected narrative of this celebrated experiment is very different from the usual verbose and pompous style of the philosophers of the period.

“Già sapevamo per innanzi (e lo sa ognuno) che il freddo da principio opera in tutti i liquori ristignimento, e diminuzione di mole, e di ciò non solamente n'avevamo la riprova ordinaria dell'aquaziente de' Termometri, ma n'avevamo fatta esperienza nell'acqua, nell'olio, nell'argentovivo, ed in molti altri fluidi. Dall'altro canto sapevamo ancora, che nel passaggio, che fa l'acqua dall'esser semplicemente fredda al rimuoversi dalla sua fluidità, e ricever consistenza, e durezza coll'agghiacciamento non solo ritorna alla mole, ch'ella aveva prima di raffreddarsi, ma trapassa ad una maggiore, mentre se le veggono rompere vasi di vetro, e di metallo con tanta forza. Ma qual poi si fosse il periodo di queste varie alterazioni, che in essa opera il freddo, questo non sapevamo ancora, ne era possibile d'arrivarvi con agghiacciarla dentro a' vasi opachi, come quei d'argento, d'ottone, e d'oro ne quali s'era fin' allora agghiacciata: Onde per non mancare di quella notizia, che pareva esser l'anima di tutte quest'esperienze, ricorremmo al cristallo, ed al vetro, sperando per la trasparenza della materia d'aver presto ad'assicurarci come la cosa andasse, mentre si poteva a ciascun movimento, che fosse apparso nell'acqua del collo, cavar subito la palla dal' ghiaccio, e riconoscer in essa quali alterazioni gli corrispondessero. Ma la verità si è, che noi stentammo assai più che non ci saremmo mai dati ad intendere, prima di poter rinvenire alcuna cosa di certo intorno a' periodi di questi accidenti. E per dirne più distintamente, il successo è da sapere, che nella prima immersione, che facevamo della palla, subito, ch'ella toccava l'acqua del ghiaccio s'osservava nell'acqua del collo un piccolo sollevamento, ma assai veloce, dopo il quale con moto assai ordinato, e di mezzana velocità s'andava ritirando verso la palla, finchè arrivata a un certo grado non proseguiva più oltre a discendere, ma si fermava quivi per qualche tempo, a giudizio degli occhi, affatto priva di movimento. Poi a poco a poco si vedea ricominciare a salire, ma con un moto tardissimo, e apparentemente equabile, dal quale senz'alcun proporzionale acceleramento spiccava in un subito un furiosissimo salto, nel qual tempo era impossibile tenerlo dietro coll'occhio, scotrendo con quell'impeto, per così dire, in istanti le decine e le decine de' gradi.” *Esperienze intorno al progresso degli artificiali agghiacciamenti, e de' loro mirabili accidenti. Saggi di naturali esperienze fatte nell'Accademia Del Cimento.* Firenze, 1691.

when heated to 8° above 40° ; in other words, the density or specific gravity of water is at its maximum at 40° .

When in the year 1683 Dr Croune repeated this experiment before the Royal Society, Hooke attributed the effect, not to any peculiarity in the expansibility of water, but to a rapid and sudden contraction of the glass bulb, which would force the water upwards in the tube;¹ a conclusion amply disproved by other forms of the experiment, especially by that suggested by Dr Hope² of Edinburgh, in which a freezing mixture was applied to the surface of water at 60° contained in a tall cylindrical glass jar. The water was cooled throughout to 40° , and then the surface sunk to 32° , and froze. But when the freezing mixture was applied to the bottom of the jar, the water became cooled throughout to 32° . If the cold be applied to the centre of the vessel, as long as the water is above 40° , the warmer part will always be at the top, but below 40° the arrangement is reversed, and the warmer part being then most dense, occupies the lower half of the vessel, and the colder portion floats upon it.

The influence of this singular anomaly, which has thus been demonstrated by unanswerable experiments, is of great extent and importance. In most of the cases in

¹ The *Histories of the Royal Society* by Sprat and Birch, contain a curious body of experimental evidence on a great variety of philosophical subjects, and detail the opinions and observations of many eminent persons upon the various researches that were carried on before that learned body. The business of the Society was formerly conducted upon a very different plan from that now pursued, and much resembled the present proceedings of the Academy of Sciences of the Royal Institute of France.

The following is Dr Birch's memorandum relating to this experiment:

February 6, 1683.

A letter of Mr Musgrave to Mr Aston, dated at New College, Oxford, was read, containing, among other things, several experiments about freezing, as that two inches of water in a tube $\frac{1}{2}$ inch diameter, expanded itself, upon freezing, $\frac{1}{8}$ higher; that a tube one inch diameter filled 6 inches, rose upon freezing, $\frac{1}{8}$ of an inch: and that half a pint of water, upon freezing, lost in weight 3ij. ʒij. gr. viij.

Dr Croune said, that having weighed three ounces of water, he found it, after freezing, to differ a scruple and half.

Sir Christopher Wren remarked, that if water were suddenly frozen, there would be less difference in weight.

Dr Croune said, that he observed water which he had put into a bolt-head, to rise higher before there was anything of freezing in it.

Mr Hooke attributed the rising of the water in the neck of the bolt-head, to the shrinking of the glass.

Dr Croune said, that the glass had been long in the cold, before, and that the water rose immediately.

Dr Wallis proposed, that an empty glass might be cooled well in a freezing liquor, in order that it might have its contraction before the water be put into it.

This was done immediately by Mr Hunt, and the water being put into a small bolt-head, rose about $\frac{1}{2}$ of an inch in the neck, though the air at that time was very warm. (*Birch's History of the Royal Society*. Vol. IV. p. 253.)

² *Edinburgh Transactions*, Vol. VI.

which nature deviates from her usual established laws, philosophy has discovered happy consequences in her aberration; and where such discovery has not been made, investigation should be upon the alert to trace the clue that is presented.

If water were obedient to the same laws of refrigeration as other less universal liquids, such as spirit, oils, and quicksilver, it must be evident, that, during the winter's cold, our rivers and lakes, instead of presenting a superficial stratum of ice, would soon become solid throughout; the continuous influence of the summer's sun would be required to produce their fluidity, and the inhabitants of the waters would annually risk extermination.

These effects are obviated by the peculiarity observed by the Academicians del Cimento. As the temperature of the earth is in winter always greater than that of the atmosphere, the cooling of large bodies of water must take place from above, by the contact of cold air and chilling blasts. The whole mass will thus be lowered to 40° , after which, the water becoming specifically lighter as it becomes colder, remains upon the surface where it sinks to 32° and is converted into a film of ice, which being a bad conductor of heat, thickens slowly, and affords further protection to the warmer fluid beneath. Those who in winter's cold accidentally fall through the ice, are surprised by the comparative warmth of the water below, and the aquatic animals that in summer sport upon the surface of their element, retire in winter to the more genial retreats which nature has thus provided.

In tracing the progress of Chemistry through its dark and early periods, the historian necessarily traverses a rugged and barren path; his chief object must be to advance, and the shortest is generally the safest road. Reaching the age of Alchemy, the prospect, though improved, is not such as to demand a very deliberate survey: its fictions, however, like those of romantic chivalry, have somewhat of reality for their basis, and by the mere increase of experimental inquiry, contributed essentially to the growth of chemical knowledge. As a science, its progress was languid until the middle of the seventeenth century, when it began to shake off the lethargy in which it had been sunk, and was turned with eager curiosity to new and more useful objects.

In the dross of the alchemical furnaces many scattered treasures were discovered, the value of which was greatly enhanced by arrangement and systematic combination. New views were thus opened to the Experimentalist; and authors, dismissing the florid exuberancies and pompous affectation of their predecessors, cultivated an unadorned and simple style, more becoming the dignity of scientific narration.

These circumstances contributed to confer a prosperous aspect on Chemical Philo-

sophy at the commencement of the eighteenth century. It was applied to the arts, and to them it gave an unexpected and vigorous impulse. It was directed to the investigation of nature, and there it discovered new beauties. It found "tongues in trees, books in the running brooks, sermons in stones, and good in everything."

SECTION III.

DISCOVERIES OF DR BLACK, RELATING TO THE CAUSE OF CAUSTICITY IN EARTHS AND ALKALIES, AND TO CERTAIN PHENOMENA OF HEAT.

THE discoveries of Dr Joseph Black form a most important epoch in the history of Chemical Philosophy; they embrace two leading subjects,—the one relating to the causticity of the earths and alkalies,—the other to the operation of heat in changing the state of bodies; in rendering solids liquids, and converting liquids into elastic or aeriform fluids.

Regarding these researches as isolated specimens of inductive philosophy, they have rarely been equalled: as influencing the progress of Chemistry, by disclosing the hidden cause of many very intricate phenomena, they have never been surpassed; and, by a happy combination of circumstances, we trace in them the distant but fertile source of those gigantic improvements of the arts, in which the perfection of the steam-engine is involved.

Of a man whose scientific character is thus pre-eminent, and in whose attainments his country has just reason to exult, history has recorded a brief but interesting memorial.¹

Dr Joseph Black was sprung from a Scottish family, transplanted first to Ireland and then to France, where he was born in 1728, on the banks of the Garonne. When twelve years of age, he was sent for education to Belfast, and afterwards to the University of Glasgow, where he entered upon the study of Physic, under the guidance of that bright ornament of medical science, Dr William Cullen. In 1750 he removed to Edinburgh; four years afterwards, he took the degree of Doctor of Physic; and, in

¹ Dr Robison's Preface to Black's *Lectures on the Elements of Chemistry*.

1756, published his *Experiments on Magnesia, Quicklime, and some other alkaline substances*, in the *Physical and Literary Essays*. In the same year Dr Cullen, having removed to Edinburgh, Dr Black returned to Glasgow to fill the Medical and Chemical chair of that University, where he was received with open arms both by the Classes and Professors. In 1764, he brought his ideas respecting the combinations of heat with ponderable matter to perfection. Speculations upon this subject had occupied his mind during a considerable period, but the difficulties of the inquiry, and the time necessarily consumed in other professional avocations, had considerably interfered with the pursuit.

In 1766, he was appointed to the Chemical Chair of Edinburgh, an office which he filled with such talent, industry, and perseverance, as not only drew an immense concourse of hearers to his class, but tended to confer upon chemistry a degree of popularity and importance, which has been greatly conducive to its promotion and extension. "His discourse," says his biographer, Professor Robison, "was so plain and perspicuous, his illustrations by experiment so apposite, that his sentiments on any subject never could be mistaken; and his instructions were so clear of all hypothesis or conjecture, that the hearer rested on his conclusions with a confidence scarcely exceeded in matters of his own experience."¹ In short, Dr Black, in his professorial capacity, was entitled to every praise, and he contributed most essentially to the foundation and increase of the reputation which the University of Edinburgh has acquired and maintained. Nor was his private character at variance with his public excellence; he was mild, amiable, and fond of conversation, whether serious or sportive; and he was not above uniting to the highest philosophical attainments, most of the

¹ Dr Black's character as a lecturer is given by his friend Professor Robison in the following terms:—"He endeavoured every year to render his courses more plain and familiar, and to illustrate them by a greater variety of examples in the way of experiments. No man could perform these more neatly and successfully. They were always ingeniously and judiciously contrived, clearly establishing the point in view, and never more than sufficed for this purpose. While he scorned the quackery of a showman, the simplicity, neatness, and elegance with which they were performed, were truly admirable. Indeed, the *simplex munditiis* stamped every thing that he did. I think it was the unperceived operation of this impression that made Dr Black's Lectures such a treat to all his scholars. They were not only instructed, but (they knew not how) delighted; and without any effort to please, but solely by the natural emanation of a gentle and elegant mind, cooperating indeed with a most perspicuous exhibition of his sentiments, Dr Black became a favourite lecturer, and many were induced, by the report of his students, to attend his courses, without having any particular relish for chemical knowledge, but merely in order to be pleased. This, however, contributed greatly to the extending the knowledge of Chemistry, and it became a fashionable part of the accomplishments of a gentleman." *Preface*, p. li.

elegant accomplishments of life. In his advanced age he often expressed a hope that he might not linger in protracted sickness, on account of the distress which, in such cases, is suffered by attending friends; and his death, which happened in his 71st year, in November 1799, is on this account the more remarkable. He was taking some milk and water, and having the cup in his hand, when the last stroke of his pulse was to be given, had set it upon his knees, and in this attitude expired without the smallest agitation.

The writings of Black, though lamentably few, are masterpieces of scientific composition. Newton was his model, and he was the first who transferred into chemistry the severe system of inductive logic, which marks the productions of that great master of natural philosophy. "In no scientific inquiries, since the date of the *Principia*, and *Optics*, do we find so great a proportion of pure ratiocination, founded upon the description of common facts, but leading to the most unexpected and important results, as in the two grand systems of Black." Averse to all hypothesis, and aware of the multitudinous facts upon which a theory that is to stand firm must be founded, Dr Black was unwarrantably slow in the formal public disclosure of his admirable researches. His tenets were fully and freely delivered to his pupils; but he very rarely intruded upon the public as an author; and his splendid achievements in the philosophy of heat are chiefly developed in his posthumous works. This silence, arising out of an over-cautious modesty which marked all his proceedings, was not favourable to the reputation of Dr Black. Faulty and incomplete copies of his lectures were circulated among his friends and admirers, which afterwards reached the hands of those who deserve another name, and by whom they were not very honourably employed.

The first researches of Dr Black, which it will be necessary to attend to, explain the cause of causticity in earths and alkalies. When chalk or limestone, which are mild insoluble tasteless substances, are heated to redness in the open fire, they are converted into quicklime, a body corrosive, soluble in water, and having an acrid flavour. Stahl, Macquer,¹ and Meyer, attributed this change to some substance absorb-

¹ Macquer was born at Paris in 1718, and died in 1784. He ranks among the most eminent scientific Chemists of the early part of the eighteenth century; and though involved in the errors of the Phlogistic school, he has written with much good sense and perspicuity on a variety of chemical subjects. His most celebrated works are, the *Elémens de Chimie Théorique*, Paris, 1749; and *Elémens de Chimie Pratique*, Paris, 1751. He also published a Chemical Dictionary. The following is all his information respecting the property possessed by quicklime of rendering the alkalies caustic. After describing the process, he observes, "Le but de cette operation, est de réunir avec le sel alcali fixe ce que la chaux a de salin et

ed from the fire,—to an acrid acid,¹—to phlogiston, and other creatures of the imagination. Dr Black's mind was turned to this subject in consequence of the discovery of magnesia. This substance made its first appearance as an Arcanum in Italy, in 1707. Valentine showed that it might be obtained from the mother-liquor of nitre, but it was supposed to be lime, until Hoffman, in 1722, pointed out several peculiarities by which it is distinguished from that earth. Hoffman prepared magnesia from bittern, or the saline liquor which remains after the separation of common salt from sea water; to this he added an alkali which precipitated the earth.² The substance which thus exists in bittern, is a compound of magnesia and sulphuric acid. It was first obtained from certain mineral springs in the neighbourhood of Epsom in Surrey, and thence called Epsom salt, but was sold at a very high price, in consequence of the small quantities so procured, until the manufacturers in the neighbourhood of Lynton obtained it from sea water; it was then largely exported to the Continent under the name of English salt.

Epsom salt was indeed long confounded with Glauber's salt, and a fraud of the manufacturers here, and in Germany, tended to keep up the confusion, for at that period Glauber's salt was rare in England, and large crystals of Epsom salt were sold under that name; but in Germany, where Epsom salt was not common, Glauber's salt, in

d'âcre."—"On le combine avec la partie la plus âcre, la plus subtile, et la plus saline de la chaux. — "Nous n'entreprendrons point ici d'expliquer pourquoi le sel alkali, que l'on combine avec la chaux, acquiert une si grande causticité. Cette question nous paroît une des plus délicates et de plus difficiles à résoudre que nous offre la Chimie. Elle tient à celle des propriétés alcalines de la chaux, et on ne peut guères espérer de la résoudre, que quand on aura acquis sur la nature de ces substance, beaucoup plus de lumières que nous n'en avons à présent." *Elémens de Chimie Pratique*, pp. 179 182.

¹ J. F. Meyers, *Chemische versuche zur nähern erkenntnis des ungelöschten kalks, der elastisch und electrischen Materie, des allerreinsten Sauerwesens, und der ursprünglichen allgemeinen saure* Hannover, 1764. In this dissertation, though published subsequently to Black's essay, the causticity of the alkalis and lime is referred to the absorption of a principle which the author calls *Causticum*, or *Acidum pingue*. Between the years 1760 and 1772, a great variety of dissertations were published in Germany upon this question, some in support of Black's doctrine, others in favour of Meyers's hypothetical absurdities. See Gren's *Systematisches Handbuch der Gesammten Chemie*. Halle, 1794. § 457.

² *Observ. Phys. Chem.* 1722.

Hoffman was the most celebrated Chemical Physician of the age. He was born at Halle in Saxony, in 1660, and died in 1742. His writings, which are voluminous, are also valuable. In 1749, they were eked out by the Genevèse Booksellers into nine folio volumes. The following are his leading Essays in Chemistry:

Dissertationes de Generatione Salium,—De Natura Nitri,—De Cinnabare Antimonii,—De Viribus Sulphuris Antimonii fixati efficacia,—De Mercurio et Medicamentis Mercurialibus. Observationum Physico-Chemicarum Collectio. Libri iii.

small crystals, was vended as English or Epsom salt. Pott of Berlin, and Du Hamel of Paris, were led into a comedy of errors in consequence of mistaking the nature of these bodies.

Dr Black found that when magnesia was prepared by precipitating a solution of Epsom salt by a mild alkali, that it effervesced with acids; but that when heated to redness it lost weight, and then dissolved without effervescence. This fact, which also holds good in respect to lime, induced him to believe that, instead of gaining any thing in the fire, something was lost by these earths. He, therefore, distilled some magnesia in a retort, but found, that although it lost weight as before, nothing but a relatively small quantity of water was found in the receiver. The experiments of Dr Hales now rushed into his mind, and it occurred to him, that some gaseous or aeriform body had escaped from the earth; and that this was the cause of its effervescing with acids,—a circumstance previously ascribed to the collision of the acid and earthy particles. He therefore put some magnesia not calcined into a bottle, with a bent tube attached to it; and thus, during the action of the acid, obtained a large quantity of an elastic fluid, in a vessel inverted in water; he found, too, that chalk, and common alkali, yielded the same kind of air. The air thus existing in these substances Dr Black called fixed air; and he proved it to be the cause of mildness in earths and alkalies. If lime be added to a mild alkali, the lime absorbs its fixed air, and renders it caustic,—an effect formerly attributed to the transfer of the fiery particles of the lime.

In the year 1750, Venel observed that selters, and other sparkling waters, when placed under the receiver of an air-pump, gave out a large quantity of air, and became flat and insipid, and he imitated them by dissolving common soda in water, and adding muriatic acid, which produced an effervescence and gave it briskness.¹ These experiments were a little antecedent to Dr Black's publication, but they by no means anticipated his discoveries.² In 1764 the conclusions of Black were verified, and his

¹ “ En 1750, Venel, Professeur de Chimie à Montpellier, reprit le fil de ses expériences en arrêtant dans l'eau le fluide dégagé des effervescences, et en imitant ainsi, par sa dissolution artificielle, les eaux minérales acidulés, mais il fit encore tous ses efforts pour prouver que c'était de l'air.” Fourcroy, *Histoire*, p. 28.

² Dr Brownrigg of Whitehaven threw out some curious hints respecting fixed air, or, as it is now called, carbonic acid, as early as 1765. In a communication to the Royal Society, printed that year in their *Transactions*, he remarks, “ that a more intimate acquaintance with those noxious airs in mines, called *lamps*, might lead to the discovery of that subtle principle of mineral waters, known by the name of their *spirit*; that the noxious exhalations termed the *Choke-damp*, he had found to be a fluid permanently elastic, and, from various experiments he had reason to conclude, that it entered the composition of the

views extended, by Dr Macbride of Dublin, who pointed out several new properties of fixed air, and demonstrated its existence in the atmosphere; for lime exposed to air gradually loses its causticity, and becomes effervescent. The operation of quick-lime as a manure depends upon its power of rendering the inert vegetable matter of the soil soluble and fit for the nourishment of young plants; an effect which it does not produce when combined with fixed air, or in the state of chalk: hence the lime should be spread quickly over the land, and not left in heaps exposed to the air, by which, as Dr Macbride has shown, it is rendered mild, and of comparatively small effect.¹

Such are the principal features of Dr Black's researches respecting the cause of mildness and causticity in earthy and alkaline substances. They constitute an important body of chemical evidence, and are established upon the satisfactory basis of analytic and synthetic proofs.

I now turn to his more elaborate investigation into the effects of heat, to inquiries so momentous in their influence upon the advancement of experimental philosophy, so replete with difficulties, and so masterly in their execution, as to raise them to the highest efforts of the human mind. I have deemed a rapid glance at the discovery of fixed air sufficient for our present purpose; for occasions will afterwards offer of descending more largely upon its nature and properties; but the investigation now before us, is that from which the towering and durable greatness of Black's name has been principally derived; and it was begun, continued, and completed, by the labour of his own hands.

In speaking of the graduation of thermometers, it was mentioned, that if snow or ice be brought into a warm atmosphere, and suffered to thaw slowly, the water which

waters of Pyrmont, Spa, and others, imparting to them that pungent taste, from which they were denominated *acidulae*, and likewise that volatile principle on which their virtues chiefly depend."

Mr Lane was the first who ascertained the solubility of iron in water, impregnated with fixed air. *Phil. Trans.* 1769. "By this means," says Sir John Pringle in his discourse on the different kinds of Air, delivered at the anniversary meeting of the Royal Society, November 30, 1773, "the nature of the metallic principle in mineral waters was clearly explained, and the whole analysis of those celebrated fountains, so often attempted by Chemists and others, and still eluding their laboured researches, was thus, in the most simple manner, brought to light."

¹ Macbride's *Experimental Essays*, 1764. The merit of this performance induced the University of Glasgow to bestow the degree of Doctor of Physic on the author.

Dr Macbride introduced some important improvements into the art of Tanning, and was the first who employed lime water in the preparatory operations of that process. He was born in the county of Antrim in 1726, and died in 1778.

runs from it is always at one temperature, that of 32° of Fahrenheit's scale. This and similar cases seem to have occupied the early thoughts of our philosopher; for his biographer informs us, that, in the oldest parcels of his notes, he found queries relating to this subject. How does it happen that, although heat is constantly flowing from surrounding bodies to the ice, its temperature is not increased? Water at 32° , when brought into a room at 60° , goes on increasing in temperature till it attains that of the circumambient air; but the ice, though exposed to exactly similar sources of heat, remains at 32° . Why, when water is cooled several degrees below its freezing point, does its temperature suddenly rise to that point, the instant that it congeals? or why is it, that, when a vessel of water is put upon the fire, a thermometer plunged into it continues to indicate increase of heat until it rises to 212° ; and the water then boils, but does not become hotter, although it remains upon the fire, and has all its former opportunities of acquiring heat? Such were the queries which Dr Black has most happily resolved.

In regard to the liquefaction of ice, he has demonstrated that, when solids pass into the liquid state, the change is always accompanied with the absorption of heat, which is concealed or becomes latent in the liquid, and is not indicated by the thermometer, which instrument, therefore, is no measure of the absolute quantity of heat. A variety of interesting and curious experiments were undertaken with a view to ascertain the quantity of thermometric heat, which thus becomes latent during the conversion of ice into water. A pound of snow at 32° was mixed with a pound of water at 172° ; the snow was melted, and the temperature of the mixture was only 52° ; so that here 140° of thermometric heat had disappeared; their effect being, not to raise the temperature of the snow, but to convert it into water. We should say, therefore, from this experiment, that water at 32° is a compound of ice, and 140° of heat as indicated by the thermometer. If water, at the temperature of 32° , be mixed with an equal weight of warm water, suppose at 200° , the resulting temperature will be the mean; $232 \div 2 = 116$; but if we use ice, the temperature will not be the mean, for 140° of heat must be subtracted from the warm water, which heat is consumed in liquefying the ice, the result, therefore, will be the same as if water at 32° and 60° were mixed, giving a mean of only 45° .

These experiments at once demonstrated the cause of many facts respecting the production of heat and cold, which, though long known, remained without any plausible explanation.

When solids become fluids, the production of cold is more or less evident, according to the rapidity of the change. Those saline bodies, for instance, which are very rapidly soluble in water, generate during their solution a considerable intensity of cold, for to become fluid they must absorb heat. When snow and salt are suddenly blended, there is an instant liquefaction, and the temperature of the substances being already low, a degree of cold equal to 0° of Fahrenheit is obtained. The production of cold by mixing snow and muriate of lime, a very soluble salt, is -40° Fahrenheit, and sufficient to freeze quicksilver even in a comparatively warm atmosphere. A mixture of 5 parts of sal ammoniac in powder, and 5 parts of nitre with 16 of water, sink the thermometer from 50° to 10° . Equal parts of nitrate of ammonia and water produce a more intense cold, and by a clever successive application of these freezing mixtures, the intense degree of cold of -91° Fahrenheit has been artificially exhibited. This is 128° below the freezing of water, and 40° below the greatest natural cold hitherto observed, which was at Hudson's Bay, where the spirit thermometer has been seen at 50° .

There are many counter illustrations of this doctrine of latent heat; in which heat is evolved during the conversion of liquids into solids. If oil of vitriol be poured upon magnesia, there is a sudden solidification of the acid by its union with the earth, and a considerable rise of temperature ensues. Water poured upon quicklime produces a similar phenomenon; and when water at perfect rest is exposed in a covered vessel to an intensely cold atmosphere, its temperature may be reduced to many degrees below its freezing point: A slight agitation causes it suddenly to become ice, and at that instant the temperature rises to 32° . A somewhat similar case is the sudden crystallization of saline solutions, during which their latent heat becomes sensible to the feeling, and is indicated by the thermometer.

In Dr Black's theory of latent heat, it is assumed that heat is matter; that it is a substance of excessive tenuity, existing in variable proportions in bodies, that when in a free state it affects our senses, and the thermometer, but that it occasionally enters into union with other substances, or is separated from them, consistent with the usual laws of chemical attraction. Thus, in fluids, it is combined or latent, but when they are converted into solids, it is separated in a free or sensible state. The other view of the question represents heat as the result of a vibrating motion among the particles of bodies; the vibrations being most rapid and extensive in the hottest bodies. In fluids the vibrations are accompanied by a motion of the particles round their own axes; and when solids pass into the fluid state, the vibratory motion or temperature is in part lost, by the communication of the rotatory motion to the particles.

Each of these hypotheses has had its able defenders and advocates ; the ideas of Newton seem to have been favourable to the latter, and many facts may be adduced in its support. The strongest are the imponderability of heat, and its continuous extrication by friction. That we discover no increase of weight in a heated body may be attributed to the insufficiency of our instruments, but its unlimited production in a variety of cases, though consonant with the hypothesis of vibration, ill agrees with that of a specific form of matter.

If a soft iron nail be beaten upon the anvil, it becomes hot and brittle, and it cannot again be rendered malleable till it has been resoftened by exposure to the fire. By those who favour the notion of a matter of heat, this has been called an *experimentum crucis*. The matter of heat, say they, is squeezed out of the nail, as water out of a sponge, but it is reabsorbed in the fire. In this experiment, however, it must be recollected, that the mechanical arrangement of the particles of the iron is considerably altered ; it is rendered very brittle ; and hence, perhaps, its insusceptibility of becoming again hot till restored to its former state or texture by the expansive power of fire.

It was not until the publication of the researches which have just been considered, that a variety of curious circumstances concerning congelation were understood. The gradual progress in the freezing of large bodies of water has been shown to depend in some measure upon the remarkable anomaly respecting its maximum of density ; but it is also materially connected with the phenomena of latent heat ; for water, before it can become ice, must part with a quantity of heat, which, if suddenly evolved, would raise the thermometer 140° . It must also be obvious, that the process of thawing suffers a similar retardation, for ice requires for its conversion into water, the absorption of 140° . of sensible heat.

Thus we see that sudden congelation and sudden liquefaction are alike prevented ; that the process must be gradual, and consequently productive of none of those evils which would result from a more rapid change.

One of the great advantages of irrigation, or meadow watering, is also explained by a reference to these principles. In an irrigated meadow, the surface of the water may be frozen ; but as water at 40° is heavier than at 32° , the former will be its temperature in contact with the grass ; and it is a temperature perfectly congenial to the functions of vegetable life. Sir Humphrey Davy examined the temperature in a water meadow near Hungerford, in Berkshire, by a very delicate thermometer. The temperature of the air, at seven in the morning, was 29° . The water was frozen above the grass ; the temperature of the soil at the roots of the grass was 43° . Thus, by the peculiarity in the re-

frigeration of water, by the defence afforded by the stratum of ice, and by the laws of congelation, the vegetables are not merely protected from the effects of an intensely cold atmosphere, but likewise from the injurious influence of sudden changes of temperature.

Congelation is to surrounding bodies a source of heat, and there is no inconsiderable mitigation of the extreme cold of air wafted over large bodies of water, by the transfer of latent to sensible heat, which must occur before they can freeze.

The theory of freezing mixtures has led to considerable improvements of their applications, and many new and curious discoveries have resulted in pursuing this inquiry. Indeed, whatever tends to disclose the laws of nature cannot ultimately fail of subjecting her more or less to the uses of life, and of manifesting more and more the wisdom of the Creator.

Having established the above facts respecting the cause of fluidity, Dr Black proceeded to the second part of his inquiry, relating to vaporisation, and pursued it with the same abilities and success. ¹ Finding the thermometer to remain stationary at 212° in boiling water, he conceived the process of ebullition to be in some respects analogous to that of liquefaction, and that the heat which did not raise the temperature of the water, entered into union with it, and became latent in the steam. If this

¹ "When we heat a large quantity of a fluid in a vessel, in the ordinary manner, by setting it on a fire, we have an opportunity of observing some other phenomena which are very instructive. The fluid is gradually heated, and at last attains that temperature which it cannot pass without putting on the form of vapour. In these circumstances, we always observe, that it is thrown into the violent agitation which we call boiling. This agitation continues as long as we throw in more heat, or any of the fluid remains, and its violence is proportional to the celerity with which the heat is supplied.

"Another peculiarity attends this boiling of fluids, which, when first observed, was thought very surprising. However long and violently we boil a fluid, we cannot make it in the least hotter than when it began to boil. The thermometer always points at the same degree, namely, the vaporific point of that fluid. Hence the vaporific point of fluids is often called their Boiling point.

"When these facts and appearances were first observed, they seemed surprising, and different opinions were formed with respect to the causes upon which they depend. Some thought that this agitation was occasioned by that part of the heat, which was more than the water was capable of receiving, and which forced its way through, so as to occasion the agitation of boiling; others, again, imagined, that the agitation proceeded from air, which water is known to contain, and which is now expelled by the heat. Neither of these accounts, however, is just or satisfactory; the first is repugnant to all our experience in regard to heat: we have never observed it in the form of an expansive fluid like air: it pervades all bodies, and cannot be confined by any vessel, or any sort of matter; whereas, the elastic matter of boiling water, can be confined by external pressure, as is evident in the experiments made with Papin's digester."

This quotation from Black's *Lectures*, (Vol. I. p. 153.), is inserted to show the state of the argument respecting the phenomena of ebullition previous to his researches.

were the case, it should be re-evolved during the condensation of steam; and thus a method was devised of ascertaining its thermometric quantity. Dr Black's experiments on this subject were very numerous. I shall allude to such as put the phenomenon in the clearest light, and are perfectly unconnected with hypothesis.

He noted the time consumed for raising a certain quantity of water to its boiling point, and then kept up the same heat till the whole was evaporated, and marked the time consumed by the process. It was thus easily computed what the temperature would have been, supposing the rise to have gone on above 212° in the same ratio as below it. The water was originally at 50° ; it boiled in four minutes, and in twenty minutes was all evaporated. In four minutes, therefore, it had gained 162° for $50^{\circ} + 162 = 212$; and in twenty minutes would have gained $162 \times 5 = 810^{\circ}$; which may, therefore, be considered as the equivalent thermometric expression of the latent heat of the steam. Another good illustration of the absorption of heat in the production of steam, is furnished by heating water under compression. It may then be raised many degrees above its ordinary boiling point; but, on removing the pressure, a portion of steam rushes out, and the remaining water has its temperature lowered to 212° .¹

Hence we learn, that the conversion of water into vapour is attended with a great loss of heat to the surrounding bodies; and although the perceptible temperature of water and steam are identical, the latter contains heat equivalent to between 800 and 900 $^{\circ}$ of perceptible or thermometric temperature. When steam is reconverted into water, this large quantity of heat is again given out; and hence a small portion of steam is capable of heating a large body of water to its boiling point. The knowledge of this fact is of great economical importance; and in breweries and other manufactories, where large bodies of water are required to be boiled, the steam, instead of being suffered, as formerly, to pass off into the air, is conveyed by pipes into other vessels of water, which it heats during its condensation. In the same way, rooms and houses are warmed by the heat evolved during the condensation of steam, in iron or copper tubes which traverse the building, and the method is at once safe and effectual.

It is in consequence of the latent heat of steam, that, in the process of distillation, we are obliged to present so large a surface for condensation; and it is not difficult, by the help of a still, to calculate the latent heat of steam. If, for instance, one hun-

¹ See Black's Experiments, which prove the absorption of heat. *Lectures*, Vol. I. p. 157, &c.

dred gallons of water at 50° be mixed with one gallon at 212° , the temperature of the water will be raised above $1\frac{1}{2}^{\circ}$. If, by the common still-tub, one gallon of water be condensed from the state of steam by one hundred gallons of water at 50° , in that case the water will be raised 11° , which is about $9\frac{1}{2}^{\circ}$ degrees more than in the former instance. Hence it appears, that the heat imparted to a hundred gallons of cold water by eight pounds of steam, would, if it could be condensed into one gallon of water, raise it 950° .

The average of the various experiments which have been made on this subject, warrants us in placing the latent heat of steam between 900° and 1000° .

These facts demonstrate that the condensation of vapour is always a heating process, and that its formation must equally be attended with the production of cold.

¹ About the year 1774, it was observed by Dr Cullen, that a thermometer moistened with spirit of wine or ether, sinks many degrees during the evaporation of those fluids; with others, the thermometer may be made to fall from 60° to 0° . The cause of this is sufficiently explained by Dr Black's theory; the ether and spirit readily pass into vapour, which requires a certain quantity of heat for its production; this is taken from the bodies it happens to be in contact with, as from the thermometer or the hand; hence the cold perceived when these fluids are applied to the body, and the advantage which results from their application in cases of burns, and inflammations. These circumstances led Dr Cullen to accelerate the evaporation of these fluids, by exposing them under the receiver of the air-pump; by placing a flask half full of ether

¹ "The Chemistry of Stahl, as it was cultivated in Germany, and France, and other countries of Europe scarcely aspired beyond the bounds within which it had been circumscribed by its original founder. A few important facts, indeed, were added, but they were either connected with medical preparations, or attracted attention solely as objects of curiosity. The great and tempting field of Philosophical Chemistry lay unexplored, when it was entered upon with ardour by Dr Cullen, who first peccived its value, and whose genius and industry, had they not been turned into another channel, would, in all probability, have been crowned with the richest discoveries. But though Dr Cullen soon abandoned his chemical pursuits for those of medicine, he was fortunate enough to have initiated into the science a man whose discoveries formed an era in chemistry, and who first struck out a new and brilliant path, which was afterwards fully laid open, and traversed with so much eclat by the British philosophers who followed his career. This fortunate pupil of Dr Cullen, was Dr Joseph Black." *Thomson, History of the Royal Society*, p. 468.

Dr Cullen's fame as a promoter of chemistry has been lost in his greater celebrity as a teacher of medicine. "Chemistry," says his biographer, Dr Anderson, "which was, before his time, a most disgusting pursuit, was, by him, rendered a study so pleasing, so easy, and so attractive, that it is now pursued by numbers as an agreeable recreation, who, but for the lights that were thrown upon it by Cullen and his pupils, would never have thought of engaging in it at all."

Cullen was born in Lanarkshire in 1712, and died at Edinburgh in 1790.

in a tumbler of water, it was found that, during the process of exhaustion, the evaporation was so rapid from the ether in the flask, as to convert the surrounding water into ice.¹

This part of the philosophy of heat, regarded in its connection with the phenomena of nature, opens pleasing views of her order and economy. In the constant evaporation from the earth's surface, from rivers, lakes, and the sea, we discern an unfailing cause of equalization of heat; the vapour thus formed, ascending to colder regions, there becomes a source of increase of temperature, and, re-assuming fluidity, is thrown upon the earth in fertilizing showers, or forming torrents among the mountains, and rivers in the valleys, is returned to the parent ocean, and again becomes active in a similar cycle of changes.

But besides these obvious and complete changes in the state of matter connected with the evolution or absorption of heat, there are others in which similar alteration of temperature is observed, without a positive change of form. Whenever the density of a body, whether solid, liquid, or aeriform, is varied, there is an equivalent variation in its latent heat. The specific gravity of soft iron is increased by hammering, and heat is evolved during the operation. A piece of Indian rubber, suddenly extended, becomes warm. If water be mixed with oil of vitriol, the density of the water is increased, and there is a very considerable augmentation of temperature. If air be suddenly compressed, it retains its elastic state, but becomes violently heated; on the other hand, if air be quickly rarified, there is an equivalent reduction in its tempera-

¹ Dr Cullen's paper is published in the *Physical and Literary Essays and Observations*. Edinburgh, 1756. Vol. II. It contains the details of many interesting experiments upon the production of cold, and he considers the power of fluids in this respect, as nearly according to the degree of volatility in each. "If to this," says he, "we join the consideration that the cold is made greater by whatever hastens the evaporation, and particularly that the sinking of the thermometer is greater, as the air in which the experiment is made is warmer, if dry at the same time, I think, we may now conclude, that the cold produced is the effect of evaporation."

A very curious and ingenious method of accelerating the evaporation of water, so as to produce a freezing temperature, has lately been devised by Professor Leslie. If we place a small basin of water under the receiver of the air-pump, its temperature will sink a few degrees during exhaustion. If a large surface of oil of vitriol be at the same time included in the exhausted receiver, the vapour of the water is rapidly absorbed by that fluid, the perfection of the vacuum is thus maintained, the production of vapour is extremely rapid, and the quantity of heat absorbed for its formation so considerable, as to allow of the conversion of the remaining water into ice. Other absorbents, such as dry clay, oatmeal, &c. may be substituted for the acid. The operation of wine and water coolers, and all cases in which diminution of temperature results from evaporation, are admirably explained upon Dr Black's *Theory of Latent Heat*.

ture. In these cases, bodies are said to change their capacities for heat ; increase of density is attended with a diminution of capacity for heat ; and diminution of density with an increased capacity. The phenomena thus presented are such as the doctrine of latent heat would lead us to expect. When a fluid is converted into a solid, there is a copious evolution of heat ; when a fluid approximates to a solid state, or where its density is increased, we might expect that heat would also be evolved. ¹

The last train of investigation, in regard to heat, which occupied Dr Black's thoughts, related to the different quantities of heat contained in different substances of the same temperature, without relation to change of density or state. A reference to an experiment will perhaps render this point more intelligible. If, for instance, a given quantity of boiling water, surrounded with ice, in sinking from 212°. to 32°. melts one pound of ice, and if the same quantity of olive oil, in passing from the same to the same temperature melts only half a pound of ice, we should conclude, that, although the thermometric temperature of the two fluids is similar, the actual quantity of heat contained in the water, and ascertainable by its effects upon the ice, is twice that contained in the oil. To signify the quantity of heat thus contained in different bodies of the same temperature, the term *specific heat* has been employed—we thus should state, from the result of the experiment alluded to, the specific heat of water to be 2. that of olive oil 1. Irvine, Crawford, Wilcke, Lavoisier, and several eminent Experimentalists of the present day, have engaged themselves in researches on this subject, but the inquiry originated with Dr Black, in the year 1762.

In these limited observations upon the discoveries of Black, I hope to have rendered myself intelligible upon those main points of his investigations, which constitute the foundation of some of the most important and refined doctrines of chemical science. The distinct object of this discourse being to record the march of chemical discovery, and not to unfold the principles of the science, it would be unwise to indulge in more extended incursions upon this fertile ground, or to trace the great trunk of his researches to its extreme ramifications. But a partial glance at the facts disclosed will show even a superficial observer the obligations we are under to the discoveries of this eminently modest and unassuming Philosopher. Of many of the most intricate phenomena of nature they furnished new, easy, and luminous explanations ; and to the arts

¹ The sinking of a thermometer suspended in the receiver of the air-pump, during exhaustion, and its subsequent rise upon the readmission of air, are noticed by Dr Cullen in the paper just quoted.

they were of unparalleled benefit; for, by developing their connection, not with the shallows merely, but with the depths of science, a new road was opened to their improvement and perfection.

Among the learned lookers-on of this period we discern many who, with independent and liberal minds, loved and patronized science for its own sake, and they were pleased at its rapid progress under the auspicious guidance of Black. Others, actuated by motives illiberal and interested, countenanced science solely upon the selfish principle of gain; the puerile and short-sighted question of *cui bono* was constantly on their lips; but even they have been silenced by the application of Black's discoveries.¹

¹ This may be the proper place to show in what way the views of Dr Black's *Theory of Latent Heat* are connected with the improvements of the steam-engine—a subject upon which I must necessarily be brief, as only in part belonging to the object of this discourse. The Marquis of Worcester is commonly regarded as the inventor of the steam-engine, but his claims are not well authenticated. It is true, that, among the Utopian schemes to be found in his *Century of Inventions*, there is a dark description of a method of raising water by steam; but we can scarcely see how this was effected, nor are there any data recorded of the success of the contrivance. Be this as it may, he who barely and obscurely hints the possibility of an undertaking cannot be regarded as forestalling him who successfully carries it into execution; and the first person, who, upon decided evidence, constructed an engine for raising water by the alternate force and condensation of steam, was Captain Savary,—who also published an account of his invention in a small tract called the *Miner's Friend*. To enter into a description of this instrument would be irrelative to my present purpose; I therefore pass on to that of Newcomen, who, in 1705, obtained a patent for an improved steam-engine. It consisted of a boiler having a cylinder placed upon it, in which was a solid plunger connected by its rod with a beam and lifting pump. The plunger was elevated by the elastic force of steam admitted from the boiler. The steam-cock being closed, a small stream of cold water was suffered to run into the cylinder, by which the steam was condensed; the pressure of the atmosphere then acting upon the surface of the plunger, forced it to the bottom of the cylinder, whence it was again raised by the readmission of steam, and so on. In 1717, Mr Henry Beighton became an improver of the steam-engine; he was probably the first who caused the steam-cock to be opened and shut by the machinery, for a man was obliged to attend Newcomen's engine for this express purpose. A few other improvements were made by different persons, but they did not affect the general action of the engine; the steam was alternately admitted into, and condensed in the main cylinder; and although defects in its power had been noticed, their cause was unknown until 1765, when, happily for the prosperity of the arts and manufactures of this country, the subject engaged the keen ingenuity of Mr Watt. The model of a Newcomen's engine fell into his hands to be repaired, and in this he presently observed the immense loss of steam occasioned by its admission into the cylinder just cooled for condensation; indeed, he went so far as to ascertain, by experiment, that half the steam of the boiler was thus lost. For, having constructed a boiler which showed the quantity of steam expended at every stroke of the engine, he found that it many times exceeded that which was sufficient to fill the cylinder. But the circumstance that excited his greatest surprise was, that the injection water gained infinitely more heat than if a quantity of boiling water, equal to that required to form the steam, had been added to it. It was probably in this dilemma that he consulted Dr Black—and the explanation of the difficulty will be obvious from the facts detailed in the text. To avail himself, therefore, of the whole power of

SECTION IV.

RESEARCHES RELATING TO THE COMPOSITION OF ATMOSPHERIC AIR.—EXPERIMENTS OF RUTHERFORD AND OF PRIESTLEY.

OF the various discoveries, which it is the object of this Dissertation to unfold, none have been more important in their consequences than those relating to the composition of atmospheric air, a subject which the ancients seem not to have thought upon, since they regarded it as an element or ultimate principle of matter.¹ In this, as in most other branches of experimental science, the advances of the human mind

the steam, it became absolutely necessary to keep up the temperature of the cylinder constantly at the boiling point of water; this he was enabled to attain, by connecting with it another vessel, exhausted of air, and immersed in cold water, into which, when communicated with the cylinder, the steam, being an elastic fluid, instantly rushes and is condensed, and, on closing its connection with the cylinder, the steam, again admitted there, now operates with full force, and suffers no further condensation. To carry off the water from this second vessel, which he calls the condenser, and to perpetuate the vacuum, Mr Watt attached to it a pump by which both the air and condensed water are removed. The engine thus altered produced the same power as one of equal dimensions on Newcomen's plan, with rather less than one-third the quantity of steam; hence was a considerable hindrance to the use of the engine materially diminished, namely, the expence of fuel. But great as was this improvement, it forms a small part of the successful achievements of Mr Watt in this department of mechanics; he amended the apparatus for boring the cylinders, and improved every part of the working gear of the engine; and he infinitely extended its applications and utility, by applying the power of steam to produce motion round an axis; but their enumeration would lead me out of the bounds of chemistry. I, therefore, hasten to the invention which may be said to have perfected the steam-engine. Steam had hitherto only been used to force the piston down,—it was returned by a weight attached to the other end of the beam. Mr Watt, in 1782, constructed an engine in which steam was used to elevate as well as to depress the piston, an alternate vacuum being formed above and below it, by the condenser, as before. An engine upon this plan, executed at Mr Watt's manufactory at Soho, near Birmingham, was first employed at the Albion Mills in 1788.

An excellent sketch of the history of the steam-engine will be found in the *Edinburgh Review*, Vol. XIII. p. 311.

¹ Thus Lucretius,—

Aera nunc igitur dicam, quid corpore toto
Innumerabiliter privas mutatur in horas:
Semper enim, quodquomque fuit de rebus, id omne
Aeris in magnum fertur mare, qui nisi contra
Corpora retribuat rebus, recitetque fluentis,
Omnia jam resoluta forent, et in aera vortæ,
Haud igitur cessat gigni de rebus, et in res
Recidere assidue, quoniam fluere omnia constat.

De Rerum Natura, Lib. V. v. 274.

have been very gradual : Mayow, in 1674, was upon the very brink of that stream of discovery, which, in 1774, carried Dr Priestley into the fastnesses of Pneumatic Chemistry. Hales, by showing the mode of disengaging and collecting gaseous fluids, removed many of the most serious obstacles which encumbered this path of research ; he was followed by Boerhaave, and afterwards by Black, who, having reached the discovery of fixed air, turned into another road of investigation. Neither Mayow, therefore, nor Hales, nor Boerhaave, nor Black, were very diligent cultivators of Pneumatic Chemistry ; they had, indeed, opened the mine, but did not explore it ; its treasures were reserved for those whose labours we are now about to recount, and were chiefly borne away by the diligent dexterity of Dr Joseph Priestley.

If we trust the quotations of Rey already cited, the necessity of air, in the process of combustion, was not only observed, but inquired into by Cæsalpinus¹ and Libavius,² as far back as the sixteenth and early part of the seventeenth century. Mayow insisted that a part only of the atmosphere was concerned in the phenomena of combustion, and found that air in which bodies had burned became unfit for the respiration of animals.³ As soon as it had been ascertained that, in the phenomena of combustion and respiration, a portion of fixed air was generated, the extinction of burning bodies, and the death of animals immersed in air, thus rendered foul, were referred to the presence of that gaseous body, its noxious qualities having been amply proved by Black and

¹ Born at Arezzo in 1519 ; died at Rome in 1603. His medical works contain some scattered chemical observations, which, however, are of little importance.

² Libavius has sometimes been cited as the most rational chemical inquirer of his age, but of this character I can find no justification in his writings upon chemical subjects ; they are either unintelligible, or trifling ; he certainly had some merit as a contriver of apparatus, and his furnaces and distillatory vessels appear to have been ingeniously devised.

He died in 1616.

³ “ Nempe animalculum quodvis una cum lucernâ in vitro includatur, ita ut aeri externo aditus præcludatur, quod faciliè factum est. Quo facto lucernam istam brevè expirantem videbimus ; neque animalculum diu tedæ ferali superstes erit. Etenim observatione compertum habeo, animal unâ cum lucernâ in vitro inclusum, haud multò plus, quam dimidium temporis istius, quo aliàs viveret spiraturum esse.” *Tractatus quinque*, cap. vii. He then goes on to show that an animal requires less air than that wanted for the combustion of a candle, and endeavours to prove that the air in which an animal has been suffocated will not support flame. “ Verisimile est autem aerem, qui vitæ sustinendæ idoneus est, etiam ad flammam conflandum ineptum esse. Quoniam ad lucernæ deflagrationem majori particularum aerearum copiâ quam ad vitam sustinendam opus sit. Advertendum est autem hic loci, quod etsi flamma vitæque iisdem particulis sustentur, non tamen propterea putandum est, sanguinis massam reverâ accensum esse.” *Tractatus quinque*, L. c. Mayow's observations on the changes produced by the breathing of animals, on the air, are not less acute than those relating to the phenomena of combustion.

others; and this opinion seemed to be sanctioned by the discovery, that air thus tainted by respiration and combustion, might, in some measure, be restored to purity by exposure to the action of lime water, which absorbed the fixed air.

In 1772, Dr Rutherford, Professor of Botany in the University of Edinburgh, published a thesis on fixed, or, as it was then called, mephitic air, from which the following passage is extracted. ¹ “ By the respiration of animals, healthy air is not merely rendered mephitic, but also suffers another change. For, after the mephitic portion is absorbed by a caustic alkaline lixivium, the remaining portion is not rendered salubrious, and although it occasions no precipitate in lime water, it nevertheless extinguishes flame, and destroys life.”

Thus we have traced the discovery of two gaseous fluids differing from common air: fixed air, discovered by Black, and *azote*, as it has since been called, by Rutherford. The former, a component part of chalk, and of the mild alcalis, the product of the combustion of charcoal, and of the respiration of animals; the latter an ingredient of atmospheric air.

It would be a wearisome and unprofitable occupation to record, even in brief terms, the transactions of a set of cavilling philosophists who started up in this country, and elsewhere, about the present period of our history; their names have sunk into oblivion, and their works were only read while recommended by novelty. Some of them I have reluctantly perused, and have found that they are rather calculated to weary the attention than to satisfy curiosity, or impart information.

I therefore hasten to one of the most remarkable and splendid epochs of chemical science, adorned by discoveries which have been rarely equalled, either in number or importance, and ushered in by a series of sterling facts and memorable investigations. The well known names of Priestley, Scheele, Cavendish, and Lavoisier, now appear upon the stage, and it will be an arduous but gratifying task to follow them through their respective parts. In this recital, a strict adherence to the dates of discoveries would neither be convenient nor useful, and I shall rather therefore deviate a little on this point, than cloud the perspicuity of my narrative, or cramp it by chronological strictness.

¹ “ Sed aer salubris et purus, non modo respiratione animalis ex parte fit mephiticus sed et aliam indolis suæ mutationem inde patitur. Postquam enim omnis aer mephiticus ex eo, ope lixivii caustici secretus et abductus fuerit, qui tamen restat nullo modo salubrior inde evadit, nam quamvis nullam ex aqua calcis præcipitationem faciet, haud minus quam antea, flammam et vitam extinguit.”

Dr Priestley's character was of so composite an order as to defy brief description or superficial delineation; he was a politician, a divine, a metaphysician, and a philosopher; and in each of these callings he displayed abilities of a peculiar and occasionally exalted description. His copious and important contributions to chemical science are the more surprising, when it is remembered that his philosophical pursuits were merely resorted to as a relaxation in his theological studies; that his mind was under the constant agitation of controversy and dispute; that he was too impatient for deep research, and too hasty for premeditated plans. But, with all these bars against him, he was a thriving wooer of science: he made more of his time than any person of whom I ever read or heard; and possessed the happy and rare talent of passing from study to amusement, and from amusement to study, without occasioning any retrograde movement in the train and connection of his thoughts.

There is another important feature in Dr Priestley's character, which may tend to throw some light upon his controversy with the French school: He possessed the strictest literary and scientific honesty; he makes frequent mention of his predecessors and contemporaries, and enumerates the ideas which he borrowed from them, and the experiments they suggested, with more than necessary accuracy and minuteness. His attachment to Chemistry seems to have been formed at Leeds,¹ about the year 1768, and between that period and the year 1772 he had added several new and highly important facts to the science, which are detailed in a long communication presented to the Royal Society in the spring of that year. It is here that he relates those research-

¹ Dr Priestley was born at Fieldhead, near Leeds, in March 1733. In 1758, he went to Nantwich in Cheshire, where he established a school, and was, for the first time, enabled to purchase some philosophical instruments, in the use of which he instructed his scholars. In 1761, he removed to Warrington, whence he made regular annual visits to the metropolis, and became acquainted with Mr Canton, Dr Franklin, and Dr Watson, who assisted him in collecting materials for his History of Electricity. In 1767, Dr Priestley went to Leeds, where his attention was especially directed to the doctrine of air, in consequence of residing near a public brewery, where he amused himself by experiments on the fixed air produced by fermentation. "When I removed from that house," says he (*Memoirs of his own Life*, p. 61), "I was under the necessity of making the fixed air for myself; and one experiment leading to another, as I have distinctly and faithfully noted in my various publications on the subject, I by degrees contrived a convenient apparatus for the purpose, but of the cheapest kind." Dr Priestley's first publication on this subject was in 1772, and related to the impregnation of water with fixed air, and the same year, in the month of March, his *Observations on different kinds of Air*, were read before the Royal Society, to which body he continued to communicate his other valuable researches. In 1794 he embarked for America, and took up his residence in Pennsylvania, where he died on the 6th of February 1804.

We have here omitted all allusions to his religious opinions and controversies, referring our readers to his *Memoirs*, and to his life in the *General Biographical Dictionary*.

es respecting the influence of vegetation upon the atmosphere, which led to entirely new views of the physiology of plants, and which displayed, in a striking light, some of those masterly and beneficent adjustments of nature, by which the different members of the creation are made to minister to each other's wants, and thus preserve that eternal harmony which marks the natural world.

As combustion and respiration were connected with the deterioration of air, it occurred to Dr Priestley to ascertain how far the growth of vegetables might be productive of similar effects.

"One might have imagined," says he, "that since common air is necessary to vegetable as well as to animal life, both plants and animals would affect it in the same manner; and I own I had that expectation when I first put a sprig of mint into a glass jar, standing inverted in a vessel of water; but when it had continued growing there for some months, I found that the air would neither extinguish a candle, nor was it at all inconvenient to a mouse which I put into it."

In experiments of this kind, Dr Priestley points out the necessity of often withdrawing the dead and dying leaves, lest, by their putrefaction, they should injure the air; he also hints at the noxious powers of some plants, especially the cabbage, of which he kept a leaf in a glass of air for one night only, and in the morning a candle would not burn in it.¹

Dr Priestley also extended his experiments to the influence of plants upon air vitiated by animal respiration and by combustion, and found that they in general did not only not contaminate the air, but that they actually restored to purity that which had been rendered impure by flame and breathing; and by showing that this change was

¹ At the beginning of the last summer, I confined, in equal portions of atmospheric air, as nearly as possible, equal surfaces of the leaves of spearmint, cabbage, mustard, bean, pea, and the vine. The plants were all thriving, and, during a great part of the day, were exposed to the sun. The bulk of the air, which was confined over water, was not altered either by the mint or vine leaves; the pea and bean leaves caused a slight diminution, but the air, in contact with the cabbage and mustard plant, was lessened by about one-fifteenth and one sixteenth its original bulk, and it extinguished a taper, which the others did not. The duration of each experiment was 48 hours. The average of the thermometer, during the period, was 52°, and of the barometer, 29,5 inches. This is not the place to enter into any explanation of these facts, or to enlarge the account of them, they prove, however, a corroboration of Priestley's assertion, that different vegetables act very differently on the air, and may be useful in adjusting some discordant results of later experimentalists. Some plants are much more gross feeders than others, and the nature of the soil in which they grow may often be, in some degree, judged of by their flavour. Those vegetables which are of very quick and luxuriant growth, and readily susceptible of the influence of manures, affect the atmosphere more than those whose growth is comparatively slow, and whose foliage is sparing.

effected by groundsel as perfectly as by mint, proved it independent of the aromatic oil to which some in their ignorance had been willing to refer it.

That actual vegetation was necessary, and the mere vegetable insufficient, he proved by exposing the pulled leaves of a mint plant to air, which were unproductive of the regeneration effected by the growing sprig.

Dr Priestley concluded from these experiments, that the noxious air resulting from combustion, and from the breathing of the different animal tribes, formed part of the nourishment of plants; and that the purity of our atmosphere, and its fitness for respiration, were materially dependent upon the functions of growing vegetables.

Mayow in 1674, and Hales in 1724, had observed the production of gaseous matter during the action of nitric acid upon the metals. I have before alluded to the very rude manner in which Mayow collected it. Hales ascertained its singular property of producing red fumes when mixed with common air. Dr Priestley resumed these inquiries, and pursued them with clever activity: he found, that, on mixing one hundred parts, by measure, of common air, with one hundred of the air procured by the action of nitrous acid on copper, which he called nitrous gas, red fumes were produced, and there was a diminution of bulk equal to ninety-two parts in the two hundred; so that one hundred and eight parts only remained.

When fixed air was thus mixed with nitrous air, there was no diminution; when air, contaminated by combustion or respiration, was used, the diminution was less than with purer air; and with air taken from different situations, Dr Priestley thought he obtained rather variable results. Hence the beautiful application of nitrous air to the discovery of the fitness of other species of air, for combustion and respiration.

It was for these discoveries that the Council of the Royal Society honoured Dr Priestley by the presentation of Sir Godfrey Copley's medal, on the 30th of November 1733.¹

* " Sir Godfrey Copley originally bequeathed five guineas to be given at each anniversary meeting of the Royal Society, by the determination of the president and council, to the person who had been the author of the best paper of experimental observation for the year past. In process of time, this pecuniary reward, which could never be an important consideration to a man of enlarged and philosophical mind, however narrow his circumstances might be, was changed into the more liberal form of a gold medal, in which form it is become a truly honourable mark of distinction, and a just and laudable object of ambition. It was, no doubt, always usual with the Presidents, on the delivery of the medal, to pay some compliment to the gentleman on whom it was bestowed, but the custom of making a set speech on the occasion, and of entering into the history of that part of philosophy to which the experiment related, was first introduced by

Sir John Pringle, who was then President, delivered, on this occasion, an elaborate and elegant discourse upon the different kinds of air, in which, after expatiating upon the discoveries of his predecessors, he points out the especial merits of Priestley's investigations : In allusion to the purification of a tainted atmosphere by the growth of plants, the President has thus expressed himself:

" From these discoveries we are assured, that no vegetable grows in vain ; but that, from the oak of the forest to the grass of the field, every individual plant is serviceable to mankind ; if not always distinguished by some private virtue, yet making a part of the whole which cleanses and purifies our atmosphere. In this the fragrant rose and deadly nightshade co-operate ; nor is the herbage nor the woods that flourish in the most remote and unpeopled regions unprofitable to us, nor we to them, considering how constantly the winds convey to them our vitiated air, for our relief and for their nourishment. And if ever these salutary gales rise to storms and hurricanes, let us still trace and revere the ways of a beneficent Being, who not fortuitously, but with design, not in wrath, but in mercy, thus shakes the water and the air together, to bury in the deep those putrid and pestilential effluvia which the vegetables on the face of the earth had been insufficient to consume." ¹

Mr Martin Folkes. The discourses, however, which he and his successors delivered, were very short, and were only inserted in the minute books of the Society ; none of them had ever been printed before Sir John Pringle was raised to the chair of the Society." *Chalmers's Biographical Dictionary.—Life of Pringle.*

Dr Franklin, in a letter upon the subject of this discovery to Dr Priestley, has expressed himself as follows :

" That the vegetable creation should restore the air which is spoiled by the animal part of it, looks like a rational system, and seems to be of a piece with the rest. Thus, fire purifies water all the world over. It purifies it by distillation when it raises it in vapours, and lets it fall in rain ; and farther still by filtration, when, keeping it fluid, it suffers that rain to percolate the earth. We knew before that putrid animal substances were converted into sweet vegetables when mixed with the earth and applied as manure ; and now, it seems that the same putrid substances, mixed with the air, have a similar effect. The strong thriving state of your mint, in putrid air, seems to show that the air is mended by taking something from it, and not by adding to it. I hope this will give some check to the rage of destroying trees that grow near houses, which has accompanied our late improvements in gardening, from an opinion of their being unwholesome. I am certain, from long observation, that there is nothing unhealthy in the air of woods ; for we Americans have everywhere our country habitations in the midst of woods, and no people on earth enjoy better health, or are more prolific." *Phil. Trans.* 1772, page 199.

Notwithstanding these researches, which have exposed some very curious facts relative to the chemical physiology of plants, it must be confessed that the causes of the renovation and equality of our atmosphere are yet by no means ascertained ; for, although some growing vegetables do, under certain circumstances, purify the air (by the absorption of carbon and the evolution of oxygen), yet, when in a state of decay, they invariably add to its contamination, and a general view of the subject would induce us to conclude,

Such were Dr Priestley's researches, and such the views to which he had been led previous to the year 1773, when he undertook the examination of the air which rises from red lead, and from red precipitate of quicksilver, when those substances are exposed to heat. This, indeed, was one of the topics upon which Hales had touched before him, but it was passed over with that hasty and superficial carelessness of which his experimental proceedings furnish so many instances, and in which he so often lost the substance by grasping at the shadow.

Dr Priestley cast his keenest eye upon the prospect now before him, and as the various objects came into view, he followed them up with more than his ordinary diligence and usual sagacity. The track he had entered upon was, indeed, of such abundant promise, as would have ensnared the attention and excited the curiosity of one less awake than our author to its interest and novelty. But he, already well initiated in the management of æriform fluids, proceeded with a rapidity which left his associates far behind, and carried him, in proud and undisputed precedence, to the goal of discovery.

The 1st of August 1774 is a *red-letter day* in the annals of Chemical Philosophy, for it was then that Dr Priestley discovered dephlogisticated air. Some, sporting in the sunshine of rhetoric, have called this the birth-day of Pneumatic Chemistry; but it was even a more marked and memorable period; it was then (to pursue the metaphor) that this branch of the science, having eked out a sickly and infirm infancy in the ill-managed nursery of the early Chemists, began to display symptoms of an improving constitution, and to exhibit the most hopeful and unexpected marks of future importance.

Dr Priestley's original opinion, that all kinds of factitious air were noxious, seems first to have been shaken by observing that a candle would burn in air procured by distilling nitre in a gun barrel; but the first experiment, which led to a very satisfac-

that they do as much harm as good, at least, if recent experiments connected with this subject are to be considered as correct.

These are the prominent features of Dr Priestley's first communication to the Royal Society respecting the different kinds of air, and had he bestowed no other contribution upon chemistry, the facts here detailed would have entitled him to a conspicuous place among the benefactors of the science. The paper is divided into several sections, in which he discusses the nature and properties of fixed air; of the air contaminated by the combustion of candles and of brimstone; of inflammable air; of air infected with animal respiration or putrefaction; of air exposed to the action of mixtures of iron filings and sulphur; of nitrous air; of air in which metals have been calcined, and which has been exposed to the action of white-lead paint; and of air procured by spirit of salt.

tory result, was conducted as follows. A glass jar was filled with quicksilver, and inverted in a basin of the same; some *red precipitate of quicksilver* was then introduced, and floated upon the quicksilver in the jar; heat was applied to it in this situation by a burning lens, and "I presently found that air was expelled from it very readily. Having got about three or four times as much as the bulk of my materials, I admitted water into it, and found that it was not imbibed by it. But what surprised me more than I can well express, was, that a candle burned in this air with a remarkably vigorous flame, very much like that enlarged flame with which a candle burns in nitrous air exposed to iron or liver of sulphur; but, as I had got nothing like this remarkable appearance from any kind of air besides this peculiar modification of nitrous air, and I knew no nitrous acid was used in the preparation of *mercurius calcinatus*, I was utterly at a loss how to account for it."¹

He afterwards obtained the same kind of air by exposing red lead and several other substances to heat, and made a number of well-devised experiments upon its properties.

Those who, for the first time, witness the effect of this air upon burning bodies, will best picture to themselves the emotion and surprise of its discoverer, when he plunged a burning taper into it. The splendour of the flame was magnificently increased, the consumption of the wax was extremely rapid, and the heat evolved much more considerable than in common air. He found, in short, that, in all cases of combustion, the process was infinitely more rapid and perfect in this kind of air, than in the ordinary atmosphere;² and he was thence induced to apply the term *dephlogisticated* to the gas he had thus obtained. He regarded it as air deprived of phlogiston, and thus accounted for its eager attraction for that principle which, during combustion, bodies were imagined to throw off. On the contrary, he accounted for

¹ *Experiments and Observations on Different Kinds of Air*, &c. Vol. II. p. 107. Birmingham, 1790.

² The following paragraph, with which Dr Priestley prefaces his account of the discovery of dephlogisticated air, presents a picture of his mind in regard to the origin of his own researches.

"The contents of this section will furnish a very striking illustration of the truth of a remark which I have more than once made in my philosophical writings, and which can hardly be too often repeated, as it tends greatly to encourage philosophical investigations; viz. that more is owing to what we call *chance*, than to, philosophically speaking, to the observation of *events arising from unknown causes*, than to any proper design or preconceived *theory* in this business. This does not appear in the works of those who write *synthetically* upon these subjects, but would, I doubt not, appear very strikingly in those who are the most celebrated for their philosophical acumen, did they write *analytically* and ingenuously." (*Exp. and Obs.* Vol. II. p. 103.)

the extinction of flame by the air discovered by Rutherford, and since termed azote¹ or nitrogen,² upon the idea that that aeriform fluid was charged or saturated with phlogiston, and he therefore called it phlogisticated air.

In enumerating the higher merits of Dr Priestley as a discoverer, we must not forget the minor advantages which his ingenuity bestowed upon experimental Chemistry. He supplied the Laboratory with many new and useful articles of apparatus, and the improved methods of managing, collecting, and examining gaseous fluids, were chiefly the results of his experience. He was the first who, with any chance of accuracy, endeavoured to ascertain the relative or specific gravities of the different kinds of air then known, he observed that dephlogisticated air was rather heavier, and phlogisticated air somewhat lighter, than that of the atmosphere; nitrous air he conceived to be nearly of the same specific gravity. His experiments were made by the help of a delicate balance and exhausted flask.

The influence upon the respiration of animals of a species of air marked by the eminent perfection with which it supports combustion, did not escape Dr Priestley's notice. On applying to it his test of nitrous air, he found the absorption produced on mixture greater than with atmospheric air, whence he conjectured its superior fitness for the support of life; he introduced mice into it, and found that they lived longer than in an equal bulk of atmospheric air, he then had the curiosity to taste the gas himself, and after two or three respirations, he felt, or fancied he felt, a peculiar sensation of lightness and ease of the chest. "Who can tell," says he, "but that in time this pure air may become a fashionable article in luxury.—Hitherto only two mice and myself have had the privilege of breathing it." To this he foolishly adds, that "the air which nature has provided for us is as good as we deserve."

We have not yet exhausted Dr Priestley's discoveries, but have seen enough to establish his claims to the title of a great benefactor to chemical science. If we compare him with his predecessor Black, he falls short in depth of judgment, but in quickness of conception, and industry of pursuit, he excels even such a standard of comparison. The one climbed the hill of discovery with slow and cautious steps, and

¹ From α and $\zeta\eta$, "destructive of life."

² *i. e.* Producer of nitric acid.

The application of dephlogisticated air to obtain intense degrees of heat, and its probable uses in medicine, were subjects which did not altogether escape Dr Priestley's attention, and he has alluded to them in the section of the work already quoted, relating to its "Properties and Uses."

Having thus obtained permanent aeriform fluids, having acid qualities, it occurred to Dr Priestley, that the volatile alcali, the substance which gives pungency to sal volatile, spirit of hartshorn, and similar compounds, might be also procured in a pure and isolated gaseous form; and, after several unsuccessful trials, he succeeded, by heating a mixture of quicklime and sal ammoniac, when a great quantity of air escaped, permanent over quicksilver, but, like the acid gases, rapidly absorbed by water.

The odour of this gas was pungent in the extreme, and it possessed the property of sal volatile, smelling salts, and similar substances, of turning vegetable blues to green. After several experiments, in which the absorbing powers of different substances in regard to this air, were tried, Dr Priestley became impatient to discover the effect of mixing it with the acid airs just described,—he imagined that he should form a neutral air. On putting this notion, however, to the proof of experiment, he was surprised to observe that when marine acid air, and the volatile alkaline air, were mixed in due proportions, they were wholly condensed into a solid. And with sulphureous air a very similar result was afforded.

Dr Priestley concluded that alkaline air was considerably lighter than acid air, because, on mixing them over mercury, he observed the former to float above the latter;

discovery of *Vitriolic Acid Air*, to show the exactness with which he acknowledges the hints and assistance of others:

“My first scheme was to endeavour to get the vitriolic acid in the form of air, thinking that it would probably be easy to confine it by quicksilver, for, as to the nitrous acid, its affinity with quicksilver is so great that I despaired of being able to confine it to any purpose. I, therefore, wrote to my friend Mr Lane to procure me a quantity of volatile vitriolic acid,” &c. “Seeing Mr Lane the winter following, he told me, that if I would only heat any oily or greasy matter with oil of vitriol, I should certainly make it the very thing I wanted, viz. the volatile or sulphureous vitriolic acid; and, accordingly, I meant to have proceeded upon this hint, but was prevented from pursuing it by a variety of engagements.

“Some time after this I was in company with Lord Shelburne, at the seat of Mons. Trudaine, at Montigny, in France; where, with that generous and liberal spirit by which that nobleman is distinguished, he has a complete apparatus of philosophical instruments, with every other convenience and assistance for pursuing such philosophical inquiries as any of his numerous guests shall chuse to entertain themselves with. In this agreeable retreat I met with that eminent philosopher and chemist, Mons. Montigni, Member of the Royal Academy of Sciences; and conversing with him upon this subject, he proposed our trying to convert oil of vitriol into vapour, by boiling it on a pan of charcoal in a cracked phial. This scheme not answering our purpose, he next proposed heating it together with oil of turpentine. Accordingly, we went to work upon it, and soon produced some kind of air confined with quicksilver; but our recipient being overturned by the suddenness of the production of the air, we were not able to catch any more than the first produce, which was little else than the common air which had lodged on the surface of the liquor, and which appeared to be a little phlogisticated by its not being much affected by a mixture of nitrous air.”

on putting a lighted candle into alkaline air the flame was enlarged, and a portion of the air appeared to burn with flame.

We have now considered the principal discoveries of Dr Priestley, upon which his title to originality rests, and it must be allowed that they are not less important than numerous. If we even consider them merely as insulated facts, they are of a very superior character, and tend greatly to enlarge our knowledge of the chemical elements of matter; but the new views of many natural and artificial phenomena, which they exposed, and which before were buried in deep obscurity, confer upon them a more exalted aspect, and have obtained for them the deserved meed of universal admiration. In perusing Dr Priestley's tracts, we find the thread of the narrative occasionally knotted with conceit, and weakened by garrulity; but these blemishes are compensated by prevailing candour and perspicuity of style: he had greatly extended the boundaries of science, and was awake to the importance of his conquests; but resisted that febrile thirst of innovation and reform, which was endemic among contemporary Chemists.

"At present," says he, in the Preface to his third volume of *Experiments and Observations*, relating to various branches of Natural Philosophy, "At present all our systems are in a remarkable manner unhinged by the discovery of a multiplicity of facts, to which it appears difficult or impossible to adjust them: We need not, however, give ourselves much concern on this account. For when a sufficient number of new facts shall be discovered, towards which even imperfect hypotheses will contribute, a more general theory will soon present itself, and perhaps to the most incurious and least sagacious eye. Thus, when able navigators have, with great labour and judgment, steered towards an undiscovered country, a common sailor, placed at the mast head, may happen to get the first sight of land. Let us not, however, contend about merit, but let us all be intent on forwarding the common enterprise, and equally enjoy any progress we may make towards succeeding in it, and, above all, let us acknowledge the guidance of that great Being, who has put a spirit in man, and whose inspiration giveth him understanding." With this quotation, sufficiently characteristic of his general style, I shall take leave of Dr Priestley, and introduce another hero of chemical history, his contemporary and great rival, Scheele.

SECTION V.

DISCOVERIES OF SCHEELE AND CAVENTISH.

AMONG those whose names became eminent in the history of chemical science during the first half of the eighteenth century, Margraaf and Bergman are entitled to particular mention. The former was a pupil of the once celebrated Neumann,¹ a man whose works are now not much thought of, but who did considerable service to the Chemistry of his day, and was evidently possessed of great diligence and some capacity. In 1733, Margraaf² pursued chemistry under Juncker at Halle, and, having returned to Berlin in 1738, we find several of his contributions in the *Transactions of the Scientific Society* of that capital. Subsequent to that period, his works were collected and published at Paris in 1762. They contain a great body of information, at that time novel and important, but they are chiefly entitled to notice as furnishing specimens of the art of analysis, which was afterwards carried to greater perfection by Bergman,³ who, indeed, may be considered as the first who pointed out the true objects of that branch of the science, and who aimed at conferring upon it the statical accuracy which has since rendered it so important and useful.

But Bergman was something more than a diligent experimentalist and acute reasoner; he was also an active patron of science, and had the merit of rescuing Scheele

¹ Casper Neumann was born at Züllichau in Prussia, in 1682, and in 1705 we find him enjoying the patronage of the King of Prussia, by whom he was sent to complete his studies at the University of Halle. In 1711 he became a pupil of Boerhaave, and shortly after visited England, whence he accompanied George I. to Hanover in 1716. In 1723 he became Professor of Practical Chemistry in the Royal College of Berlin, where he died in 1737. His works consist chiefly in dissertations on various subjects of chemical inquiry, published in the *Transactions of the Royal Society*, and in the *Miscellanea Berolinensia*. His Lectures were not printed till after his death, and proved a valuable magazine of chemical knowledge. "The author," says Dr. Lewis, who edited his works, "biassed by no theory, and attached to no opinions, has inquired by experiment into the proportions and uses of the most considerable natural and artificial productions, and the preparations of the principal commodities which depend on chemistry, and seems to have candidly and without reserve communicated all he discovered."

² Born at Berlin in 1709, where he died in 1782.

³ Torbern Bergman was born in Sweden in 1735, and died in 1784. His principal chemical papers are contained in the *Opuscula*, published at Upsal in 1779. They contain much to admire, not merely as being rich in facts and discoveries, but also on account of the general views which he takes of the mode of prosecuting philosophical inquiry, and which is so ably set forth in the preliminary essay, *De Indagando Vero*. The *Opuscula* was translated into English by Dr Edmund Cullen in 1788.

from his obscure situation, and of discerning that talent and genius in the bud which afterwards was so vigorously fruitful.

If we compare Scheele with our own countrymen, we discern him possessed of the accuracy and cool judgment of Black, conjoined with the inquisitive and busy activity of Priestley, and his success in the pursuit of science was such as might be expected to flow from this happy and rare union of opposite talents. In the number of his discoveries, their weight, and novelty, he has indeed very few equals; nor has their splendour been tarnished by time, or dimmed by the brilliant light of modern investigation.

Scheele is among the fortunate few, who, starting from an obscure original, have attained the zenith of scientific eminence. He was born in 1742 at Stralsund, where his father was a tradesman. His youthful days were passed in the house of an Apothecary at Gottenburgh, where, by singular perseverance, and that kind of industry which is prompted by strong natural inclination, he acquired a valuable stock of chemical information. In 1773, having removed to Upsal, accident brought him acquainted with Bergman, who became his friend and patron, and to whose honour be it told, that, when Scheele's reputation afterwards rose to such a height as threatened to eclipse his own, instead of listening to the voice of jealousy, which, on such occasions, is too common a frailty, he became more zealous in behalf of his rival, and more indefatigable in the service of his friend. Scheele afterwards removed to Köping, in the neighbourhood of Stockholm, where he died in 1786.

No adventitious aid, however, can be said to have contributed to Scheele's greatness. On the contrary, obstacles were opposed to his progress which would have damped the ardour, and checked the flight, of less aspiring and persevering minds; and much of his useful life was spent, "not in the soft obscurities of retirement, or under the shelter of academic bowers, but amid inconvenience and distraction, in sickness and in sorrow."

Scheele's first publication, which appeared in the *Stockholm Memoirs*¹ for the year 1771, relates to the analysis of fluor spar. The peculiarities of this substance were first noticed in 1768 by Margraaf, but the discovery of the principle upon which they depend was reserved for the superior sagacity of Scheele, who demonstrated in it the existence of lime, and an acid till then unknown, which he called fluoric acid.

¹ Scheele's *Essays* have been collected and translated into English by Dr Thomas Beddoes. London, 1786.

Scheele had applied acid of vitriol with great success to the analysis of a variety of substances, and on exposing powdered fluor spar to its action in a glass retort, he obtained the new body in question. The fluoric is one of the few acids which rapidly corrode glass; it dissolves silicious earth, a component part of glass, and forms with it an aëriform compound, permanent until it touches water, when part of the silicious earth is deposited. Scheele, not aware of this fact, at first conceived that silicious earth was a compound of fluoric acid and water, for on evolving the gas in a glass retort, and allowing it to pass into water, every bubble was coated with a film of flint; but he afterwards learned, that it was derived from the retort, which is soon eaten into holes. It is this property of fluoric acid which has led to its employment for the purpose of etching upon glass.

Scheele was next occupied in a series of researches on manganese, a mineral substance abundant in many parts of the world, but of which the nature was unknown until the appearance of his *Dissertation* upon it in 1774. This tract is full of important facts, and glitters with brilliant discoveries. We are here first informed that manganese is a metallic calx; that in its crude state it often contains a peculiar earth, to which the name *barytes* has since been applied; that the volatile alkali contains nitrogen as one of its essential component parts. But the most remarkable novelty announced in this Essay, is the discovery of a peculiar gaseous fluid of a yellow colour, which Scheele considered as the basis of the muriatic acid, conceiving the addition of phlogiston requisite to the restoration of its acid properties. This *de-phlogisticated marine acid*, as its discoverer termed it, was examined by him with some precision, and many of its leading characters ascertained, especially its power of destroying colour, which has since rendered it of so much importance to the bleacher. It has since been termed *oxymuriatic acid*, and more recently *chlorine*. Besides the valuable facts to which I have now alluded, Scheele's *Essay on Manganese* contains others of considerable interest and importance. There can be little doubt that he discovered azote about the same time as Dr Rutherford. He obtained it by exposing compounds of sulphur, and the alcalies and earths, to confined portions of atmospheric air. He found a part was absorbed, and that the remainder, though not fixed air, was still incapable of supporting combustion. He went a step farther, and demonstrated the existence of azote in the volatile alkali or ammonia, from which he obtained it by the action of certain compounds of manganese.

For our knowledge of the method of obtaining tartaric and citric acids in their pure

state from tartar and lemon juice, we are also indebted to Scheele, and for a variety of curious and interesting documents relating to some of the metallic acids, and their combinations. A compound of one of the acids of arsenic and copper was particularly described by him, and recommended as a green pigment; he prepared it by adding to a solution of blue vitriol, an alkaline solution of white arsenic.

His chemical tracts on the nature and properties of milk, his observations on ether, on the preservation of vinegar, on Prussian blue, and on the nature of the acid matter in various fruits, are all entitled to the highest praise. A just notion of their excellence may be formed by comparing them with the essays of the ablest Chemists of the present day: in regard to experimental accuracy and just conclusion, they generally stand this severe test; no small merit, when his humble means and deficient education are thrown into the balance against him.

But, of the various works of Scheele, that which is most decidedly characteristic of an inventive and original genius, is his *Chemical Observations and Experiments on Air and Fire*. Every page of this treatise has its merits, and they are distinct and peculiar; sometimes we are struck with the sagacity of his inductions, at others, with the appropriateness of his experiments. The facts are detailed in intelligible, clear, and distinct arrangement; the theoretical speculations are adduced with that caution and modesty which ensures attention, and often commands acquiescence. Nor is this essay deficient in original discoveries of the highest class. He obtained oxygen from manganese without any knowledge of Priestley's prior claims; he calls it *empyreal air*, and has detailed its properties and several modes of procuring it, with becoming accuracy and minuteness. Upon the composition of the atmosphere, and of metallic calces, he dwells at considerable length, and relates several remarkable facts concerning the chemical powers of the prismatic rays, and the radiation of terrestrial heat.¹

From one who wrote in that twilight period, when chemical philosophy was emerging from error and absurdity, we are not to expect the logical accuracy required at the present day. Scheele is sometimes hasty, and occasionally unintelligible; but seldom careless, and never ridiculous. Different men will form different estimates of Scheele's talents, and although I cannot agree with a contemporary biographer who designates

¹ In this admirable Dissertation, Scheele points out the difference between the heat which radiates from a heated surface, and that which is diffused by currents of hot air. He also shows, that terrestrial radiant heat does not pass through glass, while that of the sun does; that polished glass and metal reflect both heat and light, but that both are absorbed by a surface covered with lamp black; and that the direction of radiant heat is not diverted by a current of air.

him "as the brightest ornament of human nature, and the most extraordinary man that ever existed;" it will, I think, be generally admitted, that he was an acute and industrious philosopher, and an upright honourable man.

Of the Chemical Philosophers that adorned the last age, the Honourable Henry Cavendish¹ stands foremost in the first rank.

While Priestley and Scheele were extending the boundaries of knowledge, and pursuing that brilliant career of which I have just presented an outline, Cavendish was not less successfully employed in another train of investigation.

Van Helmont, Mayow, and Hales, had, by a series of crude and imperfect experiments, demonstrated the existence of inflammable aeriform fluids; but the nature of the peculiar principle to which they owe their inflammability had been but very imperfectly ascertained till Cavendish turned his mind to the subject, and published upon it in the *Philosophical Transactions* for 1776. The paper I allude to consists of three tracts, relating to inflammable, fixed, and nitrous air. The first is chiefly entitled to attention from its originality and importance; in the others he had been anticipated by Mayow and Black, or excelled by Priestley, Scheele, and others of his contemporaries.

By acting with dilute acids upon iron, zinc, and tin, Mr Cavendish obtained an inflammable elastic fluid. He found that it was afforded in the largest quantity by zinc, and that iron yielded more than tin; and he particularly mentions that the state of dilution, and quantity of the acid, provided it was sufficient to effect the solution of the metal, did not affect the quantity or quality of the air. He discovered in the gas thus obtained several characters, which at once distinguished it from the other varieties of air then known. It was not absorbable by water, it extinguished flame, and was fatal to animal life; but, when a candle was presented to it, it inflamed; and, when pure, burned with a blue lambent light. It was found to be the lightest known form of ponderable matter. Mr Cavendish considered it as about eleven times lighter than atmospheric air; but subsequent experiments have shown that, when it is rendered perfectly dry, and collected in a state of purity, it is about thirteen times lighter than atmospheric air. Compared with oxygen or dephlogisticated air, its relative weight is as 1 to 15.²

¹ Born in London on the 10th of October 1731.

² This circumstance has led to its application for filling air balloons, which formerly were made to ascend by distension with rarefied air—a large quantity of fuel became thus necessary, which was greatly incon-

He next proceeded to examine the results afforded by burning mixtures of inflammable and common air; and found that, in the proportion of one part of the former to about three of the latter, the mixture exploded on the contact of flame, and that, when the vessel in which this inflammation was performed was previously dry, it always became moist after the explosion.

This circumstance was noticed by Macquer in 1766, and shortly after by Priestley, but that *water* was the result of the combustion, seems first to have occurred to Mr Watt, who suggested the idea to Dr Priestley in 1783.

In January 1784, Mr Cavendish presented a paper to the Royal Society, entitled *Experiments on Air*, in which, after some preliminary remarks, he adverts to Mr Warltires' experiments, related by Dr Priestley, upon the formation of dew during the combustion of inflammable with common air, which by that gentleman was referred to the deposition of the air's moisture during its phlogistication; for by the Chemists of that period, inflammable air seems to have been considered identical with phlogiston.

The method in which Mr Cavendish pursued this inquiry was not less new than satisfactory, and the body of evidence adduced, so conclusive as to convince the most sceptical mind of the accuracy of his deductions.

To ascertain the nature of the products of the combustion of inflammable air, he had recourse to two plans: he burned it slowly and rapidly,—in the one instance, a stream of the air issuing from a small tube, was inflamed in contact with the atmosphere, or oxygen; in the other, the two gases were mixed, and suddenly detonated; and he found that, proper precautions having been taken to exclude extraneous bodies, the result was perfectly pure water; “it had no taste nor smell, and left no sensible sediment when evaporated to dryness, neither did it yield any pungent smell during the evaporation; in short, it seemed pure water.”¹ His grand discovery of the composition of water necessarily led to a variety of others, scarcely inferior in im-

venient on account of its weight; and the flame required for the rarefaction of the air inclosed in the balloon, was dangerous in the extreme—by confining inflammable air in a silk bag, of sufficient dimensions, its small specific gravity enables it to float in our atmosphere. The first ascent, with a balloon filled with hydrogen, was performed in France by M. Charles, on the 1st of December 1783—he rose to the enormous height of 10,500 feet above the earth's surface. There is a passage in Dewynt's *Sermons*, published in 1658, from which it has been concluded, that balloons were known at that early period.

¹ *Philos. Trans.* 1784. p. 129. Inflammable air has since received the name *hydrogen*, i. e. generator of water.

portance, and it tended to the elucidation of a variety of intricate phenomena in nature and art, in which that universal fluid is concerned. It was verified and established by the analytic and synthetic researches of many modern Chemists, and it became a great organ in subverting the phlogistic doctrine.

In the synthetic experiments proving the composition of water, originally devised and executed by Cavendish, he frequently observed the production of acid matter; the water formed was sour to the taste, and reddened vegetable blues; and he ascertained that these effects arose from the presence of a portion of nitrous acid. Whence this was derived remained to be proved,—whether the elements which, in one proportion, formed water, produced, in another proportion, the nitric acid, or whether it resulted from other causes. In a paper read before the Royal Society, in June 1785, Mr Cavendish sets this curious and interesting question at rest, and develops the source of the acid which appeared in his former investigations. It arose from the presence of a portion of azote which, when made to unite with oxygen, produced nitric acid. The atmosphere has already been shown to consist of azote and oxygen,—these gases are there merely mechanically mixed; when they are made to combine in the presence of water, nitric acid results.

This curious fact was proved by several experiments. That which is most simple, and most satisfactory, consisted in confining a small portion of atmospheric air in a bent tube over quicksilver, and passing the electric spark for some hours through the mixture. A diminution took place in its bulk, the mercury was corroded, and, on introducing a solution of potash, it became saturated, and yielded nitre on evaporation, a salt composed of potash and nitric acid.

These are the principal discoveries with which Cavendish enriched the science of Chemistry; they relate to the properties of hydrogen or inflammable air, to the composition of water, and to the constitution of the nitric acid. They are detailed in three communications to the Royal Society; the first stands in the *Philosophical Transactions* for 1766; the other two in the volumes for 1784 and 1785.

Those who have heard Mr Cavendish designated the Newton of Chemistry, and have only hastily perused his tracts, or witnessed imperfect illustrations of his researches, may perhaps regard him less worthy that honourable and high distinction than his contemporaries Priestley and Scheele; but a more careful examination of his writings, and a comparison of his reasoning and methods of research with those of even his most eminent fellow-labourers in science, will unanswerably support his claims, and display such peculiar and varied excellence, as must justify the highest

encomiums and most elaborate eulogies which have been bestowed on his exalted name. In his philosophical proceedings, the severest scrutineer is challenged to detect a single false step, for every conclusion he has formed, every theory that he has advanced, even every sentence he has written, will bear microscopic examination. Aware that there was no royal road to philosophic truth, he relied solely upon the light of experiment, in the path of induction, and from this he never deviates. If he excelled not his contemporaries in the number of his discoveries, he certainly equalled them in their importance, and went far before them in statical accuracy and mathematical precision : but as a Philosopher he scarcely admits of comparison ; in him most of the defects of his contemporaries were absent, and their talents concentrated ; he was “ himself alone.” In Cavendish science may boast of a follower not less disinterested than successful : his affluence was princely, and his family noble ; it was therefore not the desire of distinction in society, nor the more imperious call of necessity, but the thirst for knowledge, and love of truth, that summoned him to her banners.

Mr Cavendish did not lisp in the language of science ; it was, indeed, late before he appeared as a candidate for philosophic fame. His first paper was published in the *Transactions of the Royal Society* for 1766, when he was in his 36th year, a period of life at which Black, Priestley, and Scheele, had already acquired no inconsiderable celebrity. He was not confined to Chemistry only ; Electricity and subjects connected with Meteorology and Astronomy often occupied his thoughts and employed his pen : his last essay is on the division of astronomical instruments, published in the *Philosophical Transactions* for 1809. He was then in his 78th year, and in full possession of bodily activity and mental energy. After a few days illness, he expired on the 4th of February 1810, in the 79th year of his age.

In private life, he was unambitious, unassuming, bashful, and reserved : he was peevishly impatient of the inconveniences of eminence ; he detested flattery, and was uneasy under merited praise ; he, therefore, shunned general society, and was only familiar in a very limited circle of friends. Here he bore his great faculties always meekly : his conversation was lively, varied, and instructive ; upon all subjects of science he was at once luminous and profound ; and in discussion, wonderfully acute.

We are now about to enter upon that period of our history at which the science was reformed and modified by the French school. Of this chemical revolution I shall endeavour to present a faithful though faint outline. I shall attempt to show the grounds of innovation, to expose the weak parts of the plan, to exhibit its merits, and to com-

pare it with former theories. In the meantime, it may not be improper to take a rapid survey of the ground we have gone over, and to enumerate the materials already in the hands of the reformers.

In the early hypotheses respecting the phenomena of combustion, they were conceived to depend upon the separation of a peculiar principle, called by Stahl and his associates phlogiston; but the fallacy of these views was shown by Mayow, who, with his predecessor Rey, demonstrated the necessity of atmospheric air in the process. The attention of Chemists was drawn from these subjects early in the eighteenth century, by the new train of investigation in which Dr Black had successfully embarked, and the field of Pneumatic Chemistry, which was so eminently cultivated by Priestley, Scheele, and Cavendish, absorbed universal attention.

The ideas of the ancients concerning the Elements were now completely subverted. The air we breathe was proved to consist of two distinct aeriform fluids—the one a powerful supporter of combustion and respiration, the other extinguishing flame and exterminating life. Water, so long considered as a primitive body, had been resolved into simpler forms of matter; in short, novelties of the most attractive kind presented themselves on every side.

The discovery of hydrogen was seized upon by the advocates of phlogiston, as supporting their hypothesis, and it was generally considered as identical with that substance, which had long been hypothetical, but was now exhibited in a tangible form. The reduction of the metallic calces, by hydrogen, was considered as a powerful argument in favour of these notions, and wherever phlogiston had been supposed to be absorbed or evolved, hydrogen seemed to play the part of that imaginary principle.

The views of Priestley and Scheele were combated by a host of petty controversialists, whose names are yet extant, but whose writings are sunk into oblivion—they brought into the field an army of words, but not a single observation, founded upon fact or experiment. Mr Cavendish was more strenuously and respectably opposed: among those who stood up against his theoretical views, Mr Kirwan deserves especial mention, for he laid other departments of Chemistry under considerable obligations; but his arguments and learning were of little avail against the tried and sterling facts which he questioned; they are no creditable records to the author, but serve to show the feebleness of subtilty when opposed to the strength of truth.

SECTION VI.

INVESTIGATIONS OF LAVOISIER.

AMONG the eminent scientific characters who adorned the last century, Lavoisier has always been looked upon with high consideration. That his talents were shining, and his career brilliant, cannot be denied; but that he has those high claims to originality which we have been obliged to allow his exalted rivals, has been doubted by the generality of historians, and denied by those who have had access to the most correct information. I shall briefly notice his most important investigations, and afterward endeavour to sketch his character as a Philosopher.

The phenomena of combustion were with Lavoisier, as with his predecessors in the field of theoretical chemistry, a leading object of attention; and the theory of latent heat, devised by Dr Black, was assumed as the ground-work of his new views.

It has already been stated, that, during the conversion of solids into fluids, and of fluids into vapours, there is a considerable absorption of heat; and that, on the other hand, when vapours and liquids are restored to the fluid and solid form, the heat which they contained is evolved, or passes from the latent to the sensible or thermometric state. These views were assumed by the French school as the basis of their theory of combustion. The gas called by Priestley dephlogisticated air, and by Lavoisier oxygen, was regarded as a compound of a peculiar ponderable basis, united to the matter of light and heat. During the process of combustion, the basis was represented as combining with the combustible, augmenting its weight, and changing its properties; whilst the imponderable elements of the gas, the light and heat, were said to be developed in the form of flame.

Lavoisier instituted an extended and beautiful series of researches connected with this subject. Dr Ingenhouz had devised the brilliant experiment of burning iron wire in oxygen, but had neglected any inquiry into the change suffered by the gas and the metal. Lavoisier ascertained that the iron was converted into the black brittle substance, called *martial ethiops* by the old chemists, and that 100 grains of iron absorbed about 100 cubical inches of the gas, and increased 35 grains in weight. Hence martial ethiops appeared to be a compound of oxygen and iron.

Phosphorus was burned in the same manner. There was a considerable absorption

of the gas, and it appeared that the phosphorus had sustained a precisely equivalent increase of weight.

The general conclusions deduced from these experiments were bold, but incorrect. It was assumed that oxygen must be present in all cases of combustion; that the base of the gas always unites to the burning body, and that the heat and light essential to the aeriform state of the oxygen are consequently thrown off, or rendered sensible. With regard to the necessity of the presence of oxygen, it may be remarked, that the cases are very numerous in which bodies burn, and vividly too, independent of that principle, although it is perfectly true that, in the generality of instances, oxygen feeds the flame.

It is, therefore, more philosophical to consider combustion, or the evolution of heat and light, as a general result of intense chemical action, and as ensuing in all cases where it may be conceived that the corpuscles of bodies are thrown into violent motion, than as depending upon the presence of any distinct substance, or ensuing from the mutual actions of any appropriate forms of matter.

But farther; there are many cases in which oxygen unites to bodies, without the evolution of heat and light, as during the gradual change of some of the metals by exposure to air. And there are numerous instances in which vehement combustion ensues, not only where there is no condensation of air, but where gaseous matter is positively produced, as in the inflammation of gunpowder; and hence the theory of latent heat, as applied to the composition of gases, is insufficient to account for the phenomena.

Another weak part of the French hypothesis is that relating to the evolution of light, which, if derived from the gas, should be proportional to its consumption or solidification, whereas it depends chiefly on the combustile. Richter, Delametherie, and Gren, regarded the gas as affording the heat only, which is proportional to the quantity consumed; and they supposed the evolution of light to be derived from the combustile, and several modern chemists have espoused this explanation. Phosphorus emits much more light than hydrogen, but consumes less oxygen; hence we should regard phosphorus as containing more combined light than hydrogen. This hypothesis involves several unnecessary suppositions; but these cannot be discussed without reference to subjects which are excluded by the limits of this discourse. It may, however, here be observed, how nearly the French theory of combustion agrees with that of Rey and Mayow, in referring the increase of weight of the

combustible, to the fixation of air : this was the great obstacle in the phlogistic hypothesis, and Rey and Lavoisier overcame it by the same means.

Oxygen was not merely considered by the French school as necessary to combustion, but also as an essential ingredient in all acids (whence the term *oxygen*); but there are many acids in which no oxygen can be proved to exist, and it is now known even to form a component part of the alcalies and earths. If sulphur be burned in oxygen, it produces sulphurous acid gas : if potassium be heated in sulphurous acid gas, it robs the sulphur of its oxygen, and is converted into potash ; here oxygen is seen alternately producing an acid and an alkali,—the result depending not upon the oxygen, but upon the base with which it combines.

In detailing the discoveries of Dr Black, I was led to notice his researches concerning the production of fixed air. This gas was also examined with much attention by Priestley, Scheele, and Cavendish, and they have each made important additions to our knowledge of its sources and properties.

Lavoisier's inquiries respecting the composition of fixed air, and its production during the combustion of charcoal and of the diamond, were highly important as connected with his general theoretical views. Black had indeed ascertained that burning charcoal produced fixed air, but rested satisfied with the mere fact, and pursued not the inquiry which it naturally suggested, and which was eagerly taken up by Lavoisier at an early period of his scientific career. He burned a given weight of charcoal in a given proportion of oxygen gas confined over quicksilver, and when the vessel had cooled, he introduced a solution of potash, which absorbed the fixed air. He thus ascertained the bulk of the fixed air generated by the charcoal, and the bulk of oxygen consumed ; and, by weighing the residuum of the charcoal, he found the quantity lost by its combustion. From such experiments, he was led to regard fixed air as composed of oxygen and charcoal, in the proportions by weight of about 70 of the former and 30 of the latter. Soon after the discovery of fixed air by Black, it was demonstrated by Keir, Bergman, and Fontana, to possess acid properties ; hence it was occasionally termed aërial acid, cretaceous acid, and mephitic acid. Consistently with the principles of the new nomenclature, it received from Lavoisier the name of carbonic acid, a term implying that it is composed of charcoal and oxygen ; and this it has since retained.

The production of fixed air, or, as we may now call it, carbonic acid, during the combustion of diamond, is one of the most remarkable and important discoveries with which Lavoisier enriched chemical science. The destruction of this precious gem by

fire was demonstrated by the Florentine academicians as early as 1690 ; they exposed a diamond to the focus of a burning lens, and found that it was entirely evaporated ; and Francis the First, of Germany, witnessed the same phenomenon in the heat of a furnace. Lavoisier proved that the diamond underwent no change when air was excluded ; and that, when ignited in oxygen gas, it produced carbonic acid ; whence the inevitable conclusion that the diamond and charcoal are identical in their nature ; and that the vast difference in their appearance and mechanical qualities is the result of aggregation ; that the one is crystallized, the other in a less indurated form. Unprecedented as such an idea may seem, it is not only warranted by the experiments of Lavoisier and others, but also in some degree supported by analogy. Thus, when argillaceous earth, which is a white pulverulent substance, is aggregated by mechanical attraction into a crystalline form, it constitutes the sapphire, one of the hardest and least destructible of the gems. In one state, the earth is soft, and readily soluble in acids ; in the other, its insolubility equals its induration : but there is one invincible anomaly relating to the conducting power of the diamond and charcoal in regard to electricity ; the former ranks among the non-conductors, the latter is a conductor, and hitherto mechanical texture has not been shown, in any analogous cases, to interfere with the power of conducting electricity.

Among those who have further explored the phenomena of the combustion of the diamond, and who have verified and extended the original views of Lavoisier, we find the names of the most eminent European Philosophers. Few subjects in Chemistry have been so eagerly pursued, and the united results of different experimentalists have rarely tallied with the precision which these researches present. ¹

The discoveries of Rutherford and of Priestley, in the years 1772 and 1774, had dis-

¹ That the quantity of carbonic acid, afforded by a given weight of diamond, is the same as that yielded by a similar quantity of charcoal, is the great proof of the identity of those apparently dissimilar substances : this was demonstrated in the year 1796, by the refined and elegant experiments of Mr Tennant, whose untimely loss society has lately had to deplore. Mr Tennant was a profound philosopher, and a matchless companion,—his learning was without pedantry ; his wit without sarcasm,—he was deep, but always clear ; gentle, but never dull. To those who knew him not, it is scarcely possible to offer an adequate representation of his singularly pleasing and enlightened character,—by those who enjoyed his acquaintance, and partook of his social hours, his extent of knowledge, his happy and unrivalled talent for conversation, his harmless but brilliant flashes of merriment, and all his amiable peculiarities, can never be forgotten. Friendship will long continue to weep over his grave, and science to lament beside his tomb.

Mr Tennant was born in Yorkshire in 1761, and died at Boulogne in 1815.

See *Biographical Account* of Smithson Tennant, Esq. in Thomson's *Annals of Philosophy*, Vol. VI.

closed the elements of atmospheric air, and several experiments respecting the proportions in which they are blended, had been instituted by these, and other Philosophers. In the year 1775, Lavoisier resumed these inquiries, with a masterly and decisive hand; he heated mercury in contact with a known portion of atmospheric air; it gradually acquired a red film, which after some days ceased to form, and the metal remained unaltered; he then withdrew the fire, and suffered the vessels to cool; he found that the air had diminished in bulk, and that the quicksilver had increased in weight; that the loss of the former was equivalent to the gain of the latter—which had absorbed the oxygen of the air, leaving the azote unaltered. By such investigations he arrived, with tolerable precision, at the proportion in which these gases exist in common air, and found, that, by mixing forty-two parts, by measure, of azote with eight parts, by measure, of oxygen, he produced a compound precisely resembling our atmosphere, in its power of supporting combustion and respiration, and of contributing to the calcination of the metals.

Besides these researches and discoveries, Lavoisier was the author of many scientific papers in the *Memoirs of the Parisian Academy*. Of these a brief and hasty notice will suffice, as they relate not to the great reform of chemical theory, in which he was so conspicuous an actor, and upon which his fame and reputation have chiefly been raised: .

In 1764, the French Government proposed, as a prize question, “Which is the best method of illuminating the streets of a large metropolis?” It was answered by Lavoisier; and he was rewarded with an honorary medal. In 1768, he became a member of the Academy. In 1770, he controverted a prevailing opinion respecting the convertibility of water into earth; and, two years afterwards, published an ingenious geological essay upon the changes and stratification of the globe. In 1774, he entered upon the grand field of discovery which has occupied so much of our attention, and published an ingenious and comprehensive view of Pneumatic Chemistry. A few years afterwards, his theory of acidity, of combustion, and of oxidizement; his experiments upon the composition of water, and of the atmosphere, and his views respecting the nature and affections of heat, were successively presented to the public; and, in 1789, his work entitled *Elemens de Chimie* was given to the world. It contains a full account of his theoretical views and experimental researches.

Lavoisier was an earnest promoter of the Chemistry of the Arts. He turned his attention to the improvement of several manufactures, and his labours were rewarded by considerable success. Agriculture was with him a favourite pursuit, and he en-

deavoured to improve its processes by experimental research. He was an able Political Economist; and, for a few years, filled the office of a Commissioner of the National Treasury, with honour to himself, and benefit to his country.

The moral and social character of Lavoisier was of the most estimable cast. Contemporary historians agree in eulogizing his mild, amiable, and obliging manners; in extolling his liberality, and in praising him, as the encourager of deserving ingenuity, and the ardent patron of science and the arts.

Through the scenes of the Revolution, such a man could not expect to pass unmolested. He was rich, and therefore criminal; virtuous, and consequently offensive. In short, because his public character and private life were equally unimpeachable and blameless, he was marked out for destruction, and murdered upon the scaffold on the 8th of May 1794, in his native city of Paris, and in the 51st year of his age.

Upon these acts of iniquitous barbarity and inhuman treachery, equally degrading to the individual performers and to the beholding nation, it is neither my business nor inclination to dwell; the recital of particulars would excite disgust rather than interest; and would rather shock than inform.

We must now divest ourselves of the impressions naturally arising out of the virtues, the eminence, and the misfortunes of Lavoisier, and with unmixed attention steadily reflect upon his philosophical character. By some he has been extolled as the most original, inventive, and exalted genius of his age; by others stigmatized as an universal and dishonourable plagiarist; but these are the extremes of panegyric and malevolence, each equidistant from candour and from truth. He was doubtless an acute, sagacious, and useful Philosopher; his zeal for the welfare of science was unremitting and exemplary, and his affluence enabled him to pursue it upon an extensive and splendid scale. As an original discoverer, he bends before Black and Priestley, and was inferior to Cavendish and Scheele; but, as a theorist, he has few equals; he was comprehensive, successful, and clear. If time has shaken his opinions, and loosened his speculations, the change must be referred to the imperfect and progressive state of Chemistry, rather than to their inherent futility. In Natural Philosophy, the systems of Pythagoras, Ptolemy, Descartes, and others, have successively yielded to the satisfactory and apparently stable simplicity of the Newtonian doctrines; but the Newton of Chemistry is yet to come.

It must be regretted, that those who have censured Lavoisier with the uncandid and unacknowledged appropriation of the thoughts of others, have some grounds for

the accusation. In bringing forward his theory of combustion, why did he smother the lucid opinions of Rey and Mayow? why refuse praise and acknowledgment to Black, and Scheele, and Cavendish? or, why appropriate the discovery of oxygen, in the face of the prior, indisputable, and known claims, of his friend and contemporary Priestley? These are questions we cannot now answer; but, those who have grounded harsh, indiscriminate, and severe censure, upon such accusations, have neither been animated by the independent spirit of true philosophy, nor guided by the unbiassed love of truth. It must be remembered, that Lavoisier was never fairly confronted by these rivals and antagonists; that unintentional inadvertency often accompanies scientific ardour; that, in the eagerness of pursuit, he may have neglected that which, in a calmer hour, he would have seen, regretted, and acknowledged; and that, in the hurry of discussion and heat of controversy, he was suddenly summoned to eternity.¹

¹ Since writing the above, I have seen two scarce volumes of the posthumous works of Lavoisier in Mr Hatchett's library at Roehampton. They consist, in great measure, of extracts from, and sketches of his different papers read before the Royal Academy of Sciences, but several original Observations and Essays are also dispersed among them. They, in some degree, justify the observation which I have made in the text, that, had Lavoisier lived, he would have done merited justice to his predecessors and contemporaries, for he candidly reviews their opinions, and compares them with his own; at the same time, the following passage cannot be regarded as perfectly candid towards Rey, who, as I have shown above, founded his arguments not upon hypothesis, but upon experiment.

I insert a long quotation, that there may be no misunderstanding upon the subject.

After stating the prevailing phlogistic notions entertained at that period, he proceeds as follows: "Tel étoit l'état des connoissances, lorsqu'une suite d'expériences, entreprises en 1772 sur les différentes espèces d'air, ou de gaz qui se dégagent dans les effervescences et dans un grand nombre d'opérations chimiques, me firent connoître, d'une manière démonstrative, quelle étoit la cause de l'augmentation de poids, qu'acquéroient les métaux lorsqu'on les expose à l'action du feu. J'ignorois alors ce que Jean Rey avoit écrit à ce sujet en 1630; et quand je l'aurois connu, je n'aurois pu regarder son opinion à cet égard, que comme une assertion vague, propre à faire honneur au génie de l'auteur, mais qui ne dispensait pas les chimistes de constater la vérité de son opinion par des expériences. J'étois jeune, j'étois nouvellement entré dans la carrière des sciences, j'étois avide de gloire, et je crus devoir prendre quelques précautions pour m'assurer la propriété de ma découverte. Il y avoit à cette époque, une correspondance habituelle entre les savans de France et ceux d'Angleterre; il regnoit entre les deux nations, une sorte de rivalité qui donnoit de l'importance aux expériences nouvelles, et qui portoit quelquefois les écrivains de l'une ou de l'autre nation, à les contester à leur véritable auteur; je crus donc devoir déposer, le 1^{er} Novembre 1772, l'écrit suivant cacheté, entre les mains du Secrétaire de l'Académie. Ce dépôt a été ouvert à la séance du 5^{me} Mai suivant, et mention du tout a été faite en tête de l'écrit. Il étoit conçu en ces termes:—

"Il y'a environ huit jours que j'ai découvert, que le soufre en brûlant, loin de perdre de son poids, en acquéroit au contraire; c'est à dire, que d'une livre de soufre, on pouvoit retirer beaucoup plus d'une livre d'acide vitriolique, abstraction faite de l'humidité de l'air; il en est du même du phosphore: cette augmentation de poids vient d'une quantité prodigieuse d'air qui se fixe pendant la combustion, et qui se combine avec les vapeurs.

Though these considerations do not exculpate our philosopher, they must be allowed to extenuate his imputed failings—they should induce us rather to soften the asperities of his scientific character, than to magnify its faults—instead of rejoicing that he was not perfect, we should delight in his excellence; and should estimate his character as a Philosopher, not so much by the means he employed, as by the noble effects produced.

Among many other subjects which engaged the attention of Lavoisier and his associates, that of reforming the nomenclature of Chemistry deserves to be noticed as highly beneficial to the promotion of the science, and as tending materially to facilitate its acquisition. I am inclined, however, to think that, upon this point, too much credit has been given to the French school; rage for innovation, and not zeal for improvement, seems often to have guided the undertaking; and terms, once deemed faultless, now appear not less absurd and objectionable than the fanciful names employed by the alchemical writers.

As principals in the formation of the new nomenclature, we find the names of Guyton Morveau¹ and Fourcroy, two men who may certainly be considered as ornaments of their age and country. The former, amidst varied avocations, prosecuted Chemistry

“ Cette découverte que j’ai constatée par des expériences que je regarde comme décisives, m’a fait penser que ce qui s’observoit dans la combustion du soufre et du phosphore, pouvoit bien avoir lieu à l’égard de tous les corps qui acquièrent du poids par la combustion et la calcination : et je me suis persuadé, que l’augmentation de poids des *chaur* métalliques, tenoit à la même cause. L’expérience a complètement confirmé mes conjectures : j’ai fait la réduction de la litharge dans des vaisseaux fermés, avec l’appareil de Hales, et j’ai observé qu’il se dégagéoit, au moment du passage de la *chaur* en métal, une quantité considérable d’air, et que cet air formoit un volume au moins mille fois plus grand que la quantité de litharge employée. Cette découverte me paroissant une des plus intéressantes qui ait été faite depuis Stahl, j’ai cru devoir m’en assurer la propriété, en faisant le présent dépôt entre les mains du Secrétaire de l’Académie, pour demeurer secret jusqu’au moment où je publierai mes expériences.”

(Signé) “ LAVOISIER.”

“ En rapprochant cette première notice de celle que j’avois déposée à l’Académie le 20^me Octobre précédent, sur la combustion du phosphore, du mémoire que j’ai lu à l’Académie à sa séance publique de Pâques 1773, enfin, de ceux que j’ai successivement publiés, il est aisé de voir, que j’avois conçu dès 1772, tout l’ensemble du système que j’ai publié depuis sur la combustion. Cette théorie à laquelle j’ai donné de nombreux développemens en 1777, et que j’ai portée, presque dès cette époque à l’état où elle est aujourd’hui, n’a commencé à être enseignée par Fourcroy, que dans l’hyver de 1786 à 1787; elle n’a été adoptée par Guyton Morveau, qu’à une époque postérieure; enfin, en 1785 Berthollet écrivoit encore dans le système du phlogistique. Cette théorie n’est donc pas, comme je l’entends dire, la théorie des Chimistes François : elle est la mienne, et c’est une propriété que je réclame auprès de mes contemporains et de la postérité.”

¹ Born at Dijon in 1737. Died at Paris in 1815. See *Life* by Dr Granville in the *Journal of Science and Arts*, Vol. III. p. 249.

with successful diligence, and, had he given nothing else to the science, his name deserves to be transmitted to posterity, as the inventor of the means of destroying infection by acid vapours, the efficacy of which he first pointed out in the year 1773. His first essay on the reform of nomenclature was published in the *Journal de Physique* for May 1782, and although it was strenuously opposed by the colossal power of the Royal Academy of Paris, the plan was not only afterwards approved, but prosecuted by the eminent Chemists of that metropolis. The different papers and correspondence relating to this subject are, in many respects, curious and interesting from the difference of opinion which prevailed respecting the terms he adopted, and the ultimate benefit likely to result from the reformation.

Fourcroy¹ is a well known name in the chemical world; his works rank among the most celebrated which France has produced in the science of Chemistry, though they are sometimes deficient in candour, and sometimes in correctness. His labours were important, and his discoveries numerous, but they are, in many respects, so closely interwoven with those of contemporary Philosophers, that I have deemed it expedient to waive farther notice respecting their objects and merits.

I have now brought my narrative to the conclusion of the last century, about which period Electricity began to assume importance as a chemical agent, and the *Voltaic* apparatus became a necessary implement of the laboratory. To this source, the new aspect which chemical science now wears, may principally be referred, and the historian, who shall in aftertimes record the advances that have been made in Chemistry during the last eighteen years, will recite triumphs of the human mind never excelled, and rarely equalled.—I am apprehensive that the inquisitive eye will detect several omissions in the foregoing pages, although I have diligently endeavoured to record every important event in the general history of the science. Of many who have attained deserved eminence in the exclusive pursuit of its distinct branches, no mention has been made: I have looked with attention into their works, and am well aware of their individual merits; but I should have swerved from the principal object of this Dissertation, that of recording discoveries, had I attempted even the superficial enumeration of their infinitely varied applications.

Supplement

TO THE

ENCYCLOPÆDIA BRITANNICA.

CHEMISTRY.

Chemistry. **S**INCE the publication of the article Chemistry, in the *Encyclopædia Britannica*, that science has been so much extended and improved as to have acquired an entirely new character. And although we have given a full account of a most important branch of this improvement in our article under the head ATOMIC THEORY, it is conceived, that a connected view of the present state of Chemical Philosophy, will add much to the utility of the present work. This we shall endeavour to give in the most condensed form consistent with perspicuity.

Chemistry takes cognizance of all changes in the constitution of matter, whether effected by heat, mixture, or other means. Its general range, therefore, is so extensive, and the individual cases, requiring explanation, so numerous, that *Arrangement* is of the first consequence to its successful study; and, in the present state of our knowledge, it will be found most convenient to begin with the discussions relating to the general powers or properties of matter, and afterwards to proceed to the examination of individual substances, and to the phenomena which they offer when presented to each other under circumstances favourable to the exertion of their mutual chemical agencies.

The powers and properties of matter, connected with chemical changes, may be considered under the heads of

1. Attraction.
2. Heat.
3. Electricity.

I. ATTRACTION.

Attraction may be regarded as acting at sensible
VOL. III. PART I.

and at insensible distances. In the former case, it is called gravitation. It is the power by which substances are propelled towards the earth; it exists in all known forms of matter, and acts directly as the mass, and inversely as the square of the distance: And, when restrained by *inertia*, it preserves the planetary bodies in their orbits, presides over their movements, and tends to confer upon the system of the universe that consummate harmony which the genius of Newton has unveiled.

Attraction is also exerted at insensible distances, and among the minutest atoms of matter. It thus preserves the form and modifies the texture of solids, gives a spherical figure to fluids, and influences the mechanical characters of bodies; and, when it operates upon *dissimilar* particles, it produces their union, giving rise to new and infinitely varied productions.

The results of attraction, as relating to the forms of matter, are influenced by the circumstances under which it has taken place. Sometimes the particles are, as it were, indiscriminately collected; in other cases they are beautifully arranged, giving rise to regular and determinate figures. In this case, bodies of the same composition invariably affect the same form; hence we are often enabled to infer the composition of a substance from accurate inspection of its external or mechanical characters. The regular polyhedral solids thus resulting from the influence of attraction upon certain kinds of matter, are usually called crystals, and the bodies are said to be susceptible of *crystallization*. To enable the particles of bodies to assume that regular form which crystals exhibit, it is obvious, that they must have freedom of motion, and, accordingly, the first

Chemistry. step towards obtaining a body in its crystalline form, is to confer upon it either the liquid or æriform state. The former is usually effected by solution in water; the latter by exposure to heat. When common salt is dissolved in water, its particles may be regarded as disposed at regular distances throughout the fluid; and if the quantity of water be considerable, the particles will be too far asunder to exert reciprocal attraction; in other words, they will be more powerfully attracted by the water than by each other. If we now slowly get rid of a portion of the water by evaporation, the saline particles will gradually approach each other, and they will aggregate according to certain laws, producing a regular solid of a cubic form. The regularity of this figure will be influenced by the rapidity of the evaporation; if the process be slowly conducted, the particles unite with great regularity; if hurried, the crystals are irregular and confused. In common cases, the evaporation may be continued till a pellicle forms upon the surface of the solution, which indicates, that the attraction of the saline particles for each other, is becoming superior to their attraction for the water. The formation, therefore, of a superficial pellicle is the common criterion of the fitness of a solution for crystallization; but where the object is to obtain very regular and very large crystals, the evaporation must be much slower, and carried to much less extent; even spontaneous evaporation, or that which takes place at common temperatures, must be resorted to. There are certain bodies which may be dissolved or liquified by heat, and, during slow cooling, may be made to crystallize. This is the case with many of the metals, and with sulphur. Some other substances, when heated, readily assume the state of vapour, and, during condensation, present regular crystalline forms, such as iodine, benzoic acid, camphor, &c. The hardness, brilliancy, and transparency of crystals, often depend upon their containing water, which sometimes exists in large quantities. Thus, sulphate of soda, in the state of crystals, contains more than half its weight. This is called *water of crystallization*. Some salts part with it by simple exposure to a dry air, when they are said to effloresce; but there are other salts which deliquesce, or attract water from the atmosphere.

Crystallization.

Crystallization is accelerated, by introducing into the solution a nucleus, or solid body, upon which the process begins; and manufacturers often avail themselves of this circumstance. Thus we see sugar-candy crystallized upon strings, and verdigris upon sticks. There are cases in which it is particularly advantageous to put a few crystals of the dissolved salt into the solution, which soon cause a crop of fresh crystals; and in some instances, if there be two salts in solution, that will most readily separate, of which the crystals have been introduced. A strong saline solution, excluded from the air, will frequently crystallize the instant that air is admitted, —a circumstance referred to atmospheric pressure. In other cases, agitation produces the same effect.

Chemist These phenomena seem connected with the doctrine of latent heat. The presence of light also influences the process of crystallization. Thus we see the crystals collected in camphor bottles in druggists' windows always most copious upon the surface exposed to light; and if we set a solution of nitre in a room which has the light admitted only through a small hole in the window-shutter, crystals will form most abundantly upon the side of the basin exposed to the aperture through which the light enters.

We may now proceed to examine the structure of crystallized bodies, upon which the *Theories of Crystallization* are founded. This inquiry exposes the connecting link between Chemical and Mechanical properties of bodies.

It is commonly observed, that crystallized bodies affect one form in preference to others. The fluor spar of Derbyshire crystallizes in cubes: so does common salt. Nitre assumes the form of a six-sided prism, and sulphate of magnesia that of a four-sided prism. These forms are liable to vary. Fluor spar and salt crystallize sometimes in the form of octoëdra, and there are so many forms of carbonate of lime, that it is difficult to select that which most commonly occurs.

Romé de Lisle referred these variations of form to certain truncations of an invariable primitive nucleus; and Gahn afterwards observed, that when a piece of calcareous spar was carefully broken, all its particles were of a rhomboidal figure. This induced Bergman to suspect the existence of a primitive nucleus in all crystallized bodies. When Haüy* entered this field of inquiry, he not only corroborated the opinions of Bergman, and submitted former hypotheses to experimental proof, but traced with much success the laws of crystallization, and pointed out the modes of transition from primitive to secondary figures.

Those who are in the habit of cutting and polishing certain gems, have long known that they only afford smooth surfaces when broken in one direction; and that in others the fracture is irregular and uneven. This is the case with crystallized bodies in general. If we attempt to split a cube of fluor spar with the blade of a knife, assisted by a hammer, we shall find that it will only yield kindly in the direction of the solid angles; and pursuing the division in these directions, an octoëdron will be the resulting figure, as in this diagram. In splitting a six-sided crystal of calcareous spar, we find that, of the six edges of the superior base, three alternate edges only will yield to the blow; those, for instance, marked *a, b, c*; and the division will take place in a plane inclined at an

Chemistry. angle of 45° . The three intermediate edges resist this division. But in dissecting the inferior base of the crystal, the intermediate edges will alone yield, namely a, b, c . If we continue this dissection in the same directions, we shall at length obtain the obtuse rhomboid, which is seen in this diagram in its relative situation to the including prism.

We thus then arrive at the primitive form of the calcareous spar, and from whatever secondary form it has been obtained, it is always a rhomboid, having obtuse angles of 105° . But an obtuse rhomboid is also the primitive form of other bodies, as of pearl spar, iron spar, and tourmalin. But here the inclination of the surface points out a difference. Thus the primitive angle of pearl spar is $106^\circ 5'$, of iron spar 107° ,* and of tourmalin $113^\circ 10'$.

These instances show the necessity of being provided with instruments for measuring the angles of crystals with nice accuracy; they are termed *goniometers*. The reflective goniometer, invented by Dr Wollaston,† is the most useful of these instruments. It enables us to determine the angles even of minute crystals with great accuracy; a ray of light reflected from the surface of the crystal being employed as radius, instead of the surface itself.

In following the method above described, having obtained six primitive forms,

1. The cube, parallelopipedon, &c.
2. The tetraëdron.
3. The octoëdron.
4. The hexangular prism.
5. The rhombic dodecaëdron.
6. The dodecaëdron with triangular faces.

These primitive forms, by further mechanical analysis, may be reduced to three *integral elements*.

1. The parallelopiped, or simplest solid, having six surfaces parallel, two and two.
2. The triangular, or simplest prism, bounded by five surfaces.
3. The tetraëdron, or simplest pyramid, bounded by four surfaces.

The secondary forms are supposed to arise from

Chemistry. decrements of particles taking place on different edges and angles of the primitive forms. Thus a cube, having a series of decreasing layers of cubic particles upon each of its six faces, will become a dodecaëdron, if the decrement be upon the edges; but an octoëdron, if upon the angles; and by irregular intermediate and mixed decrements, an infinite variety of secondary forms would ensue.

But in crystallography we meet with appearances which Haüy's theory but imperfectly explains. A slice of Derbyshire spar, for instance, obtained by making two successive and parallel sections, may be divided into acute rhomboids; but these are not the primitive form of the spar, because, by the removal of a tetraëdron from each extremity of the rhomboid an octoëdron is obtained. Thus, as the whole mass of fluor may be divided into tetraëdra and octoëdra, it becomes a question which of these forms is to be called primitive, especially as neither of them can fill space without leaving vacuities, nor can they produce any arrangement sufficiently stable to form the basis of a permanent crystal. To obviate this incongruity, Dr Wollaston‡ has very ingeniously proposed to consider the primitive particles as spheres, which, by mutual attraction, have assumed that arrangement which brings them as near as possible to each other. When a number of similar balls are pressed together in the same plane, they form equilateral triangles with each other; and if balls so placed were cemented together and afterwards broken asunder, the straight lines in which they would be disposed to separate, would form angles of 60° with each other. A single ball, placed any where on this stratum, would touch three of the lower balls, and the planes touching their surfaces would then include a regular tetraëdron. A square of four balls, with a single ball resting upon the centre of each surface, would form an octoëdron, and upon applying two other balls at opposite sides of this octoëdron, the group will represent the acute rhomboid. Thus the difficulty of the primitive form of fluor, above alluded to, is done away, by assuming a sphere as the ultimate molicula. By oblate and oblong spheroids other forms may be obtained. The subject of crystallization has more lately engaged the attention of Mr J. F. Daniell,|| and his researches have produced some singular confirmations of Dr Wollaston's hypothesis. If an amorphous piece of alum be immersed in water, and left quietly to dissolve, at the end of about three weeks we shall observe that it has been unequally acted upon by the fluid: the mass will present the forms of octoëdra, and sections of octoëdra, as it were carved or stamped upon its surface, as seen in these figures:

* Wollaston. *Phil. Trans.* 1812.

† *Phil. Trans.* 1809.

‡ *Phil. Trans.* 1813. Some acute remarks on the formation of crystals may be found in Hooke's *Micrographia*.

|| *Quarterly Journal of Science and the Arts*, Vol. I.

Chemistry.

This appearance is produced when the attraction of the water for the solid is nearly counterbalanced by its mechanical texture. The crystals produced by this species of dissection, are highly curious from their modifications and relative positions, as the same group present the primitive form as well as its truncations and decrements. Other salts yield other figures, and by more complicated chemical action, as of acids upon carbonate of lime, the metals, &c. analogous results are obtained. Here, then, instead of dividing a crystal by mechanical force, its structure is gradually developed by the process of solution. In these cases two circumstances are particularly remarkable: the crystals are different, and their forms vary with the different faces of the original mass. In one direction we observe octoëdra and sections of octoëdra; in another, parallelograms of every dimension, modified with certain determinate intersections.

If, in either of these positions, we turn the mass upon its axis, the same figures will be perceived at every quadrant of a circle; and, if we suppose the planes continued, they will mutually intersect each other, and various geometrical solids will be constructed. In this way, alum alone furnishes octoëdrons, tetraëdrons, cubes, four and eight-sided prisms, either with plain or pyramidal terminations, and rhombic parallelopipedons. It is evident, then, that no theory of crystallization can be admitted, which is not founded upon such a disposition of constituent particles, as may furnish all these modifications, by mere abstraction of certain individuals from the congeries, without altering the original relative position of those which remain; and these conditions may be fulfilled by such an arrangement of spherical particles, as would arise from the combination of an indefinite number of balls endued with mutual attraction, and no other geometrical solid is adequate to the purpose; and where bodies furnish crystals differing from the octoëdral series, an analogous explanation is furnished, by supposing their constituent particles to consist of oblate spheroids, whose axes bear different proportions to each other in different substances. Hence we may also conclude, that the internal structure of all crystals of the same body is alike, however the external shapes differ. In corro-

boration of the above hypothesis, we may remark, that the hexaëdron is, of all geometrical figures, that which includes the greatest capacity under the least surface. If, therefore, the ultimate particles of crystalline bodies be spheres or spheroids, the greatest possible number in the least space will be included in this form. It is probable that the exterior shape of every crystal is determined by the nucleus first formed by a certain definite number of particles, which, by the power of mutual attraction, overcome the resistance of the medium in which they were suspended, or from which they were separated. This number may vary with the solvent, or other contingent circumstances. Four spherical particles, thus united, would balance each other in a tetraëdral group, six in an octoëdral group, and each would present particular points of attraction to which all subsequent deposits would be directed. Now, let us imagine two nuclei formed in the same solution, whose axes run in contrary directions; their increase will consequently be in contrary directions, and each will attract a particular system of particles from the surrounding medium. If these two systems should cross each other in their course, a greater number will be brought within the sphere of mutual reaction at the point of junction, and they ought to arrange themselves in the least possible compass. The facts here answer to the theory. If we select any crystals, having others crossing them nearly at right angles, and separate them, the points of junction invariably present an hexaëdral arrangement.

In connection with chemistry, the theory of crystallization opens a new avenue to the science, and frequently enables us to ascertain directly that which, independent of such aids, could only be arrived at by an indirect and circuitous route. We frequently read the chemical nature of substances in their mechanical forms. To the mineralogist, an intimate acquaintance with the crystalline forms and modifications of natural bodies is essentially requisite. Indeed, the theory of crystallization may be considered as one of the great supports of that useful branch of natural history, and it is to the indefatigable exertions of Haüy that much of its present perfection is to be referred. In the arts, the process of crystallization is turned to very valuable account, in the separation and purification of a variety of substances.

We have hitherto considered Attraction as disposing the particles of bodies to adhere, so as to form masses or aggregates, and, in many instances, to arrange themselves according to peculiar laws, and to assume regular geometrical figures. We are now to regard this power as operating upon dissimilar particles, as presiding over the composition of bodies, and as producing their chemical varieties. This is **CHEMICAL ATTRACTION OR AFFINITY**. If, into a glass vessel, exhausted of air, be introduced some sulphur, and copper filings, and heat be applied so as to melt the former, it will presently combine with the latter. We observe, as the results of this attraction between the sulphur and copper, 1. That the substance produced has not the intermediate properties of its elements, but that it presents new characters. 2. That much heat and light are evolved during the

Chemist

Chemistry. mutual action. 3. That sulphur and copper will unite in certain proportions only. In liquids and gases, similar changes of properties may be exhibited, and, in many cases, a change of form or state results. Thus the combination of æriform bodies produces a solid, as when muriatic and ammoniacal gases produce the solid salt called muriate of ammonia. Solids also produce liquids, and liquids gases. In all cases of true chemical combination, the properties of the compound differ essentially from those of its component parts, and a series of new bodies, possessed of distinct and peculiar characters, are produced. Such operations are not confined to art. Nature presents them on an extended scale, and, in connection with the functions of life, renders them subservient to the most exalted purposes.

The new chemical powers, therefore, that bodies acquire in consequence of combination, are often extremely remarkable, and can only be learned by *experiment*. It frequently happens that inert bodies produce inert compounds, and that active substances remain active when combined; but the reverse often occurs. Thus oxygen, sulphur, and water, in themselves tasteless and comparatively inert, produce *oil of vitriol* when chemically combined; and potash, which is a powerful caustic when combined with oil of vitriol, forms a salt possessed of little activity. As chemical action takes place among the ultimate or constituent elements of bodies, it must obviously be opposed by the cohesion of their particles, and chemical attraction is often prevented by mechanical aggregation. A piece of the metal antimony, put into the gas called chlorine, is only slowly and superficially acted upon; but if the mechanical aggregation be previously diminished, by reducing the metal to powder, it in that state rapidly unites with the gas, and burns the instant that it is introduced. Heat increases the chemical energies of bodies. Its effects are sometimes only referable to the diminution of adhesion by expansion, but in other cases are peculiar and complicated, as will be shown under the sections on **HEAT** and **ELECTRICITY**.

Bodies are possessed of very different attractive powers, and if several be brought together, those which have the strongest mutual affinities enter first into union. Thus, if nitric acid be poured upon a mixture of lime and magnesia, it dissolves the former in preference to the latter earth. The knowledge of this fact enables us to separate bodies when united, or to perform the process of decomposition. Thus, if I add an aqueous solution of lime to a solution of magnesia in nitric acid, the latter earth is thrown down or precipitated, and the lime occupies its place in the acid.

Decomposition is effected under a variety of circumstances, and by many methods; but it is commonly described by chemists as **SIMPLE** and **COMPLEX**, or **SINGLE** and **DOUBLE**.

In cases of simple attraction or affinity, one body separates another from its combination with a third. Thus, when potash is added to a solution of sulphate

Chemistry. of zinc (composed of sulphuric acid and oxide of zinc), the oxide of zinc is separated, and sulphate of potash is produced.

In cases of double decomposition, two new compounds are produced; as when a solution of nitrat of barytes is mixed with solution of sulphate of soda, the results are a precipitate of sulphate of barytes, and a solution of nitrat of soda.

It is obvious, from the uniform results of chemical action, that affinity must be governed by certain definite laws, by which its results are determined, and upon which its uniformity depends. Attention was first called to this subject by Mr Higgins in 1789.* He conceived that chemical attraction only prevailed between the ultimate particles of simple elementary matter and between compound atoms; and, in applying this idea to chemical theory, he expressed by numbers the relative forces of attraction subsisting between the different kinds of ultimate particles and atoms of matter.

These views were subsequently extended and improved by Mr Dalton,† and have since engaged the attention of some most eminent chemical philosophers; among whom we may enumerate Gay Lussac and Berzelius, Davy, Wollaston, and Thomson.

The atomic doctrine, or theory of definite proportions, has been much blended with hypothetical views; but it will be most satisfactorily and usefully considered as an independent collection of facts.

When bodies unite so as to form one compound only, that compound, under whatever circumstances it is produced, whether by nature or art, always contains the same relative proportions of its components; and where two bodies unite in more than one proportion, the second, third, &c. proportions are multiples or divisions of the first. This law is well exhibited in the combinations of gaseous bodies. These are seen to unite in simple ratios of volume. Water is composed of hydrogen and oxygen, and 1 part by weight of the former gas, unites to 7,5 of the latter. The specific gravity of hydrogen, compared with that of oxygen, is as 1 to 15: it is obvious, therefore, that one volume of hydrogen unites to half a volume of oxygen, and that the composition of water will be represented by weight and volume thus:

I.	7,5
H.	O.

Muriatic acid gas consists of 1 part by weight of hydrogen, and 33½ by weight of chlorine. The relative specific gravities of these gases are as 1 to 33,5. It is obvious, therefore, that they combine in equal volumes, and that muriatic acid gas may be thus represented.

1.	33,5
H.	C.

* *A Comparative View of the Phlogistic and Antiphlogistic Theories, &c.* London, 1789.

† *New System of Chemical Philosophy.* Manchester, 1810.

Chemistry.

Carbonic acid unites to potash in two proportions, and forms two definite compounds. In the one, 70 parts of potash are combined with 30 of carbonic acid; in the other, 70 of potash are united to 60 of carbonic acid. Lead combines with oxygen in three proportions; the first compound consists of 100 lead + 8 oxygen, the second of 100 + 12, the third of 100 + 16.

Bodies are always obedient to these laws of union; and, in whatever way they are produced, their component parts exist in the same relative proportions.

HEAT.

Heat may be considered as a power opposed to Attraction, for it tends to separate the particles of bodies; and whenever a body is heated, it is also expanded. Expansion is the most obvious and familiar effect of heat; and it takes place, though in different degrees, in all forms of matter. Solids are the least expansible,—liquids expand more readily than solids,—and gases or æriform bodies more than liquids. When a body has been expanded by heat, it regains its former dimensions when cooled to its former temperature. Different bodies expand differently when equally heated. The metals are the most expansible solids; but among them, zinc expands more than iron, and iron more than gold. Liquids differ also in their relative expansibilities. Ether is more expansible than spirit of wine, and spirit more than water, and water more than mercury. Those liquids are generally most expansible which boil at the lowest temperature. In all pure gaseous bodies, the rate of expansion for similar increase of temperature is similar: 100 measures of air, when heated from the freezing to the boiling point of water, suffer an increase in bulk = 37,5 parts at mean pressure. As heat increases the bulk of all bodies, it is obvious that change of temperature is constantly producing changes in their density or specific gravity, as may be easily demonstrated in fluids where there is freedom of motion among the particles. If I apply heat to the bottom of a vessel of water, the heated part expands and rises, while a cold or denser stratum occupies its place. In air, similar currents are continually produced, and the vibratory motion observed over chimney pots, and slated roofs which have been heated by the sun, depends upon this circumstance. The warm air rises, and its refracting power being less than that of the circumambient colder air, the currents are rendered visible by the distortion of objects viewed through them. There is only one strict exception to the general law of expansion by heat, and contraction by cold; this is in the case of water, which expands considerably when it approaches its freezing point.

Principle of Thermometers.

If we mix equal quantities of the same fluid at different temperatures, the cold portion will expand as much as the hot portion contracts, and the resulting temperature is the mean; so that it appears, that as much heat as is lost by the one portion is gained by the other. Upon this principle, thermo-

Chemistry.

meters are constructed. A common thermometer consists of a tube terminated at one end by a bulb, and closed at the other. The bulb and part of the tube are filled with a proper liquid, generally mercury, and a scale is applied, graduated into equal parts. Wherever this instrument is applied to bodies of the same temperature, the mercury, being similarly expanded, indicates the same degree of heat. In dividing the scale of a thermometer, the two fixed points usually resorted to are the freezing and boiling of water, which always take place at the same temperature, when under the same atmospheric pressure. The intermediate part of the scale is divided into any convenient number of degrees; and it is obvious, that all thermometers thus constructed will indicate the same degree of heat when exposed to the same temperature. In the centigrade thermometer, this space is divided into 100°; the freezing of water being marked 0, the boiling point 100°. In this country we use Fahrenheit's scale, of which the 0° is placed at 32° below the freezing of water; which, therefore, is marked 32°, and the boiling point 212°, the intermediate space being divided into 180°. Another scale is Reaumur's; the freezing point is 0°, the boiling point = 80°. These are the principal thermometers used in Europe. Each degree of Fahrenheit's scale is equal to $\frac{4}{9}$ of a degree on Reaumur's; if, therefore, the number of degrees on Fahrenheit's scale, above or below the freezing of water, be multiplied by 4, and divided by 9, the quotient will be the corresponding degree of Reaumur.

Fahrenheit.

Reaumur.

$$68^{\circ} - 32^{\circ} = 36 \times 4 = 144 \div 9 = 16^{\circ}$$

$$212^{\circ} - 32^{\circ} = 180 \times 4 = 720 \div 9 = 80^{\circ}$$

To reduce the degrees of Reaumur to those of Fahrenheit, they are to be multiplied by 9, and divided by 4.

Reaumur.

Fahrenheit.

$$16^{\circ} \times 9 = 144 \div 4 = 36^{\circ} + 32^{\circ} = 68$$

$$80 \times 9 = 720 \div 4 = 180 + 32 = 212$$

Every degree of Fahrenheit is equal to $\frac{5}{9}$ of a degree on the Centigrade scale; the reduction, therefore, is as follows.

Fahrenheit.

Centigrade.

$$212 - 32 = 180 \times 5 = 900 \div 9 = 100^{\circ}$$

Centigrade.

Fahrenheit.

$$100 \times 9 = 900 \div 5 = 180 + 32 = 212^{\circ}$$

Where a thermometer is intended to measure very low temperatures, spirit of wine is employed in its construction, as that fluid has never been frozen, whereas the low temperature at which it boils renders it unfit for measuring high temperatures. Quicksilver will indicate 500°, but freezes at — 40°. Air is sometimes resorted to as indicating very small

Chemistry. changes of temperature; and of air thermometers, that described by Professor Leslie,*

Differential Thermometer.

under the name of the Differential Thermometer, is the best. It consists of two large glass bulbs containing air, united by a tube twice bent at right angles, containing coloured sulphuric acid. When a hot body approaches one of the bulbs, it drives the fluid towards the other. The great advantage of this instrument in delicate experiments is, that general changes of the atmosphere's temperature do not affect it, but it only indicates the difference of temperature between the two balls.

The relative quantities of heat which different bodies in the same state require to raise them to the same thermometric temperature, is called their specific heat, and those bodies which require most heat are said to have the greatest capacity for heat. That the quantity of heat in different bodies of the same temperature is different, was first shown by Dr Black, in his lectures at Glasgow, in 1762.

It has been stated as a proof of the accuracy of the thermometer, that equal volumes of the same fluid, at different temperatures, give the arithmetical mean, on mixture. Thus, the temperature of a pint of hot and a pint of cold water is, after mixture, as near as possible half-way between the extremes. The cold water being of a temperature of 50°, and the hot of 100°, the mixture raises the thermometer to 75°. But if a pint of quicksilver at 100° be mixed with a pint of water at 50°, the resulting temperature is not 75°, but 70°; so that the quicksilver has lost 30°, whereas the water has only gained 20°. Hence, it appears, that the capacity of mercury for heat is less than that of water; and if the weight of the two bodies be compared, which are as 13,3 to 1, their capacities will be to each other as 19 to 1.

In cases where the specific heat of bodies is to be ascertained, it is convenient that water should be the standard of comparison, or = 1. The following is

a general formula for determining the specific heat of bodies, from the temperature resulting from the mixture of two bodies at unequal temperatures, whatever be their respective qualities. Multiply the weight of the water by the difference between its original temperature, and that of the mixture. Also, multiply the weight of the other liquid, by the difference between its temperature and that of the mixture; divide the first product by the second, and the quotient will express the specific heat of the other substance, that of water being = 1. Thus, 20 ounces of water at 105°, mixed with 12 ounces of spermaceti oil at 40°, produce a temperature of 90°. Therefore, multiply 20 by 15 (the difference between 105 and 90) = 300. And multiply 12 by 50 (the difference between 40 and 90) = 600. Then 300, ÷ 600, = $\frac{1}{2}$, which is the specific heat of oil; that is, water being 1, oil is 0,5.

The capacities of bodies for heat have considerable influence upon the rate at which they are heated and cooled. Those bodies which are most slowly heated and cooled have generally the greatest capacity for heat. Thus, if equal quantities of water and quicksilver be placed at equal distances before the fire, the quicksilver will be more rapidly heated than the water, and the metal will cool most rapidly when carried to a cold place. Upon this principle, Professor Leslie ingeniously determined the specific heat of bodies, observing their relative times of cooling a certain number of degrees, comparatively with water, under similar circumstances.

The Calorimeter, invented by Lavoisier for determining the specific heat of bodies, is an inaccurate instrument.

The capacity of gases and vapours differs with the nature of the gas, and with its density. In gases dilatation produces cold, and compression excites heat. A thermometer suspended in the receiver of the air-pump sinks during exhaustion, and sudden compression of air produces heat sufficient to inflame tinder. In liquids, too, condensation diminishes capacity for heat; hence the mixture of spirit and water, and of oil of vitriol and water, evolves heat. The increased capacity which air acquires by rarefaction has its influence in modifying natural temperatures. The air, becoming rarer as it ascends, absorbs its own heat, and hence becomes cold in proportion as it recedes from the earth's surface: thus moisture, rain, or snow, are thrown down on the mountain tops.

When different bodies are exposed to the same source of heat, they suffer it to pass through them with very different degrees of velocity, or they have various conducting powers in regard to heat. Among solid bodies, metals are the best conductors. And silver, gold, and copper, are better conductors than platinum, iron, and lead. Next to the metals, we may, perhaps, place the diamond,—then glass,—then siliceous and hard stony bodies in general,—

* *Experimental Inquiry into the Nature and Propagation of Heat*, by John Leslie. London, 1804, p. 9, &c.

Chemistry. then soft and porous earthy bodies, and wood,—and, lastly, down, feathers, wool, and other porous articles of clothing.

Liquids and gases are very imperfect conductors of heat, and heat is generally distributed through them by a change of specific gravity, as before stated.

If we apply heat to the upper surface of any fluid, it will with great difficulty make its way downwards. Count Rumford considered fluids as non-conductors of heat; but the more accurate researches of Dalton, Hope, Murray,* and Thomson,† have demonstrated that they do conduct, though very imperfectly. Experiments on the conducting power of air are complex and difficult, and the results hitherto obtained are unsatisfactory. They are interfered with by several circumstances presently to be noticed.

The different conducting powers of bodies is shown in the application of wooden handles to metallic vessels, or a stratum of ivory or wood is interposed between the hot vessel and the metal handle. The transfer of heat is thus prevented. Heat is confined by bad conductors; hence clothing for cold climates consists of woollen materials; hence, too, the walls of furnaces are composed of clay and sand. Confined air is a very bad conductor of heat; hence the advantage of double doors to furnaces, to prevent the escape of heat, and of a double wall, with an interposed stratum of air, to an ice house, which prevents the influx of heat from without. From the different conducting powers of bodies in respect to heat, arise the sensations of heat and cold experienced upon their application to our organs, though their thermometric temperature is similar. Good conductors occasion when touched a greater sensation of heat and cold than bad ones. Metal feels cold because it readily carries off the heat of the body; and we cannot touch a piece of metal immersed in air of a temperature moderate to our sense.

Latent Heat. Heat has great influence on the forms or states of bodies. When we heat a solid, it becomes fluid or gaseous; and liquids are converted into æriform bodies or vapours. Dr Black investigated this effect of heat with singular felicity, and his researches rank among the most admirable effects of experimental philosophy.‡ During the liquefaction of bodies, a quantity of heat is absorbed, which is essential to the state of fluidity, and which does not increase the sensible or thermometric temperature. Consequently, if a cold solid body, and the same body hot and in a liquid state, be mixed in known proportions, the temperature after mixture will not be the proportional mean, as would be the case if both were liquid, but will fall short of it; much of the heat of the hotter body being consumed in rendering the colder solid liquid, before it produces any effect upon its *sensible temperature*. Equal parts of water at 32° and of water at 212° will produce on mixture a mean tem-

perature of 122°. But equal parts of ice at 32° and of water at 212° will only produce (after the liquefaction of the ice) a temperature of 52°, the greater portion of the heat of the water being employed in thawing the ice, before it can produce any rise of temperature in the mixture. To heat thus *insensible*, or *combined*, Dr Black applied the term *latent heat*. The actual loss of thermometric heat in these cases was thus estimated; a pound of ice at 32° was put into a pound of water at 172°; the ice melted, and the temperature of the mixture was 32°. Here the water was cooled 140°, while the *temperature* of ice was unaltered; that is, 140° of heat disappeared,—their effect being not to increase temperature, but to increase fluidity.

The same phenomena are observable in all cases of liquefaction, and we produce artificial cold, often of great intensity, by the rapid solution of certain saline bodies in water. When fluids are converted into solids, their latent heat becomes sensible; congelation therefore is to surrounding bodies a heating process, and liquefaction a cooling process.

When liquids are heated, they acquire the gaseous form, and become invisible elastic fluids, possessed of the mechanical properties of common air. They retain this form or state, as long as their temperature remains sufficiently high, but reassume the solid form when cooled again. Different fluids pass into the æriform state at different temperatures, or their boiling points are different; they are also regulated by the density of the atmosphere. If we diminish atmospheric pressure, we lower the boiling point. When the barometer is at 28 inches, water will boil at a lower temperature than when it is at 31 inches. Water under mean atmospheric pressure boils at 212°. At the top of Mont Blanc, Saussure found that it boiled at 187°, so that the heights of mountains, and even of buildings, may be calculated by reference to the temperature at which water boils upon their summits. The Reverend Mr Wollaston has lately described to the Royal Society, the method of constructing a thermometer of extreme delicacy, applicable to these purposes. In the vacuum of an air-pump, fluids boil at temperatures considerably below their ordinary boiling points.

The conversion of a liquid into vapour, is always attended with great loss of thermometric heat, and, as liquids may be regarded as compounds of solids and heat, so vapours may be considered as consisting of a similar combination of heat with liquids; in other words, a great quantity of heat becomes latent during the formation of vapour. This is easily illustrated by immersing a thermometer into a vessel of water placed over a lamp. The quicksilver rises to 212°, the water then boils, and although the source of heat remains, neither the water nor the steam acquire a higher temperature than 212°; the heat then becomes latent, and is consumed in the formation of steam.

* *System of Chemistry*, Vol. I.

† *System of Chemistry*, Vol. I.

‡ Black's *Lectures*, edited by John Robison, LL.D. Edinburgh, 1803.

Chemistry. To ascertain the absolute loss of thermometric heat in this case, Dr Black * instituted the following experiments: He noted the time required to raise a certain quantity of water to its boiling point; he then kept up the same heat till the whole was evaporated, and marked the time consumed by the whole process; it was thus computed to what height the temperature would have risen, supposing the rise to have gone on above 212° , in the same ratio as below it, and as the temperature of the steam was the same as that of the water, it was fairly inferred that all the heat above 212° was essential to the constitution of aqueous vapour. Dr Black estimated this quantity at about 810° , that is, the same quantity of heat which is required for the total evaporation of boiling water at 212° would be sufficient to raise the water 810° above its boiling point, or to 1022° had it continued in the liquid state. There are other means of ascertaining the latent heat of steam, which lead us to place it between 900 and 1000° .

When steam is again condensed, or when vapours reassume the liquid state, their latent heat becomes sensible, and in this way it is obvious that a small quantity of steam will, during its condensation, communicate heat sufficient to boil a large quantity of water.

The cold produced by evaporation is, under certain circumstances, very great. Spirit of wine and ether, which readily evaporate, produce considerable cold during that process. Upon this principle, wine coolers and similar porous vessels, refrigerate the fluids they contain; and thus, by accelerating the evaporation of water, by exposing it under an exhausted receiver, containing bodies that quickly absorb its vapour, Professor Leslie has contrived to effect its congelation; the heat required for the conversion of one portion of the water into vapour being taken from the other portion, which is thus reduced to ice.

The heat given off by steam during its condensation, is often advantageously applied to warming buildings, and is at once safe, salubrious, and economical. In many natural operations the conversion of water into vapour, and the condensation of vapour in the form of dew and rain, is a process of the utmost importance, and tends considerably to the equalization of temperature over the globe.

Nothing is known of the nature or cause of heat. It has been by some considered as a peculiar fluid, to which the term *Caloric* has been applied; and many phenomena are in favour of the existence of such a fluid. By others, the phenomena above described have been referred to a *vibratory motion* of the particles of matter, varying in velocity with the perceived intensity of the heat. In fluids and gases the particles are conceived to have a motion round their own axis. Temperature, therefore, would increase with the velocity of the vibrations, and increase of capacity would be produced by the motion being performed in greater space. The loss of tem-

perature during the change of solids into liquids and gases, would depend upon loss of *vibratory motion*, in consequence of the acquired *rotatory motion*.

Upon the other hypothesis, temperature is referred to the quantity of *caloric* present; and the loss of temperature which happens when bodies change their state, depends upon the chemical combination of the caloric with the solid in the case of liquefaction, and with the liquid in the case of conversion into the aëriform state. †

ELECTRICITY.

If a piece of sealing-wax and of dry warm flannel be rubbed against each other, they both become capable of attracting and repelling light bodies. Glass rubbed upon silk exhibits the same phenomena. In these cases the bodies are said to be *electrically excited*. If two pith-balls be electrified by touching them with the sealing-wax or with the flannel, they repel each other; but if one pith-ball be electrified by the wax and the other by the flannel, they attract each other. The same applies to the glass and silk; it shows a difference in the electricities of the different bodies; and the experiment leads to the conclusion, that bodies similarly electrified repel each other, but that, when dissimilarly electrified, they attract each other.

If one ball be electrified by sealing-wax rubbed by flannel, and another by silk rubbed with glass, those balls will repel each other; which proves, that the electricity of the silk is the same as that of the sealing-wax. But if one ball be electrified by the sealing-wax and the other by the glass, they then attract each other, showing that they are oppositely electrified.

The terms vitreous and resinous electricity were applied to these two phenomena; but Franklin, observing that the same electricity was not inherent in the same body, but that glass sometimes exhibited the same phenomena as wax, and *vice versa*, adopted another term; and, instead of regarding the phenomena as dependent upon two electric fluids, referred them to the presence of one fluid, in excess in some cases, and in deficiency in others. To represent these states, he used the terms plus and minus, positive and negative. When glass is rubbed with silk, a portion of electricity leaves the silk, and enters the glass. It becomes positive, therefore, and the silk negative; but when sealing-wax is rubbed with flannel, the wax loses and the flannel gains. The former, therefore, is negative, the latter positive. All bodies in nature are thus regarded as containing the electric fluid, and, when its equilibrium is disturbed, they exhibit the phenomena just described.

Very delicate pith-balls, or stripes of gold leaf, are usually employed in ascertaining the presence of electricity; and, by the way in which their divergence is affected by glass or sealing-wax, the kind or

Supposed
Cause of
Heat.

* Lectures, pp. 145, et seq.—Dr Black's *Researches on the Latent Heat of Steam*, led Mr Watt to his great improvement of the steam-engine, of which an account is given in the *Lectures*, page 184.

† See Davy's *Elements of Chemical Philosophy*.

Chemistry. state of electricity is judged of. When properly suspended or mounted for delicate experiments, they form an electrometer. A considerable improvement in the insulation of the gold leaves has been introduced by the late Mr Singer, and is described in his *Elements of Electricity*. London, 1814.

Some bodies suffer electricity to pass through their substance, and are called *conductors*. Others only receive it upon the spot touched, and are called *nonconductors*. The former do not, in general, become electric by friction, and are called *nonelectrics*. The latter, on the contrary, are *electrics*, or acquire electricity by friction. They are also called *insulators*. The metals are all conductors; glass, sulphur, and resins, are nonconductors. Water, damp wood, spirit of wine, and some oils, are imperfect conductors.

There are many substances which show signs of electricity when heated, as the tourmalin, topaz, diamond, boracite, &c.; and in these bodies the different surfaces exhibit different electrical states. Whenever one part of a body, or system of bodies, is positive; another part is invariably negative; and these opposite electrical states are always such as exactly to neutralize each other. Thus, in the common electrical machine, one conductor receives the electricity of the glass cylinder, and the other that of the silk rubber, and the former conductor is positive and the latter negative; but if they be connected, all electrical phenomena cease.

If an insulated conductor be electrified, and an uninsulated conductor be opposed to it, there being between the two a thin stratum of air, glass, or other nonconductor, the uninsulated conductor, under such circumstances, acquires an opposite electrical state to that of the originally electrified insulated conductor. In this case, the uninsulated body is said to be electrified by *induction*; and the induced electricity remains evident, until an explosion, spark, or discharge happens, when the opposite electricities annihilate each other. Induced electricity may thus be exhibited through a long series of insulated conductors, provided the last of the series be communicated with the earth.

Thus, in the following diagram, A may represent the positive conductor of the electrical machine. B, C, and D, three insulated conductors, placed at a little distance from each other. D having a chain touching the ground, then the balls 1, being positive, will attract the balls 2, which are rendered negative by induction. Under these circumstances, each of the conductors becomes polar, and the balls 3 are positive, while 4 are negative, 5 positive, 6 negative, &c. The central points of the conductors, B, C, D, are neutral. When these opposite electrical states have arrived at a certain intensity, sparks pass between the different conductors, and the electrical phenomena cease.

Chemistry. Upon the principle of induction it is that the accumulation of electricity in the Leyden phial is effected. It consists of a thin glass jar, coated internally and externally with tinfoil to within a short distance of its mouth. When the inner surface is rendered positive by union with the conductor of the electrical machine, the exterior becomes negative by induction. When the inner and outer surfaces are united by a conductor, all electrical accumulation is annihilated by a spark, and the two opposite states are found to have been precisely equivalent. If one Leyden jar be insulated with its internal surface connected with the positive conductor, another jar may be charged from its exterior coating; and if this second jar be insulated, a third may be charged from its exterior coating, and so on for any number of jars, provided always that the exterior coating of the last jar be connected with the ground. In this case, a polar arrangement, similar to that of the conductors just described, will have been formed, glass being the medium of induction instead of air.

Let CP be the positive conductor of the electrical machine, and *a*, *b*, *c*, three insulated Leyden phials, the outer coating of *c* being connected with the ground; it is then obvious, that there will be the same polar state as in the conductors just noticed; that the insides of *a*, *b*, and *c*, will be positive, and the outsides negative; and that, consequently, on removing the jars from each other, they will all be similarly charged, and that if the three inner surfaces *p*, *p*, *p*, and the three outer surfaces *n*, *n*, *n*, be united, the whole may be discharged as one jar.

Electricians employ the term *quantity* to indicate the absolute quantity of electric power in any body, and the term *intensity* to signify its power of passing through a certain stratum of air or other ill-conducting medium.

If we suppose a charged Leyden phial to furnish a spark when discharged of one inch in length, we should find that another uncharged Leyden phial, the inner and outer coating of which were communicated with those of the former, would, upon the same quantity of electricity being thrown in, reduce the length of the spark to half an inch; here, the quantity of electricity remaining the same, its *intensity* is diminished by one-half, by its distribution over the larger surface.

There are many other sources of electricity than those just noticed. Whenever bodies change their forms, their electrical states are also altered. Thus the conversion of water into vapour, and the longelation of melted resins and sulphur, are processes in which electricity is also rendered sensible.

When an insulated plate of zinc is brought into contact with one of copper or silver, it is found,

Chemistry. after removal, to be positively electrical, and the silver or copper is left in the opposite state. If the nerve of a recently killed frog be attached to a silver probe, and a piece of zinc be brought into the contact of the muscular parts of the animal, violent convulsions are produced every time the metals thus connected, are made to touch each other.

If a piece of zinc be placed upon the tongue, and a piece of silver under it, a peculiar sensation will be perceived every time the two metals are made to touch.

In these cases the chemical properties of the metals are observed to be affected. If a silver and a zinc wire be put into a wine glass full of dilute sulphuric acid, the zinc wire only will evolve gas; but upon bringing the two wires in contact with each other, the silver will also copiously produce air bubbles.

If a number of alternations be made of copper or silver leaf, zinc leaf, and thin paper, the electricity excited by the contact of the metals will be rendered evident to the common electrometer. Also, if plates of zinc and copper be regularly arranged, with moistened flannel between each pair of plates, we shall observe that, having made 50 or 60 such alternations, the same effect will be produced, and that the zinc plate will give a positive, and the copper extreme a negative charge to the gold leaf electrometer.

If the same arrangement be made with strong brine, or a weak acid, it will be found, on bringing a wire communicating with the last copper plate into contact with the first zinc plate, that a spark is perceptible, and also a slight shock, provided the number of alternations be sufficiently numerous. This is the Voltaic apparatus.

On immersing the wires from the extremes of this apparatus into water, it is found that the fluid suffers decomposition, and that oxygen gas is liberated at the positive wire or pole, and hydrogen gas at the negative pole.

All other substances are decomposed with similar phenomena, the inflammable element being disengaged at the negatively electrical surface; hence it would appear, upon the principle of similarly electrified bodies repelling each other, and dissimilarly electrified bodies attracting each other, that the inherent or natural electrical state of the inflammable substances is *positive*, for they are attracted by the *negative* or oppositely electrified pole; while the bodies called supporters of combustion, or acidifying principles, are attracted by the positive pole, and, therefore, may be considered as possessed of the negative power.

All bodies which exert powerful chemical agencies upon each other, when freedom of motion is given to their particles, render each other oppositely electrical when acting as masses. Hence Sir H. Davy, the great and successful investigator of this branch of chemical philosophy, has supposed that electrical and chemical phenomena,

Chemistry. though in themselves quite distinct, may be dependent upon one and the same power, acting in the former case upon masses of matter, in the other upon its particles.

We refer to the article *ELECTRICITY* for the theory of the Voltaic Pile; a subject involved in considerable difficulty. In it the *quantity* of electricity is always increased by extending the surface of the plates, while the *intensity* rapidly augments with the increase of the number of alternations. Both quantity and intensity, in this instance, are greatly influenced by the chemical action of the fluid upon the plates; the acid bodies, as possessing highly opposite states to those of the metals, are most efficacious; and, in experiments made with the great Voltaic apparatus at the Royal Institution, it has been found that 120 plates, rendered active by a mixture of one part of nitric acid, and three of water, produced effects equal to 480 plates, rendered active by 1 part of nitric acid, and 15 of water.

We have as yet no plausible hypothesis concerning the *cause* of electrical phenomena, though the subject has engaged the attention of the most eminent philosophers of Europe. They have been by some referred to the presence of a peculiar fluid existing in all matter, and exhibiting itself by the phenomena which have been described, whenever its equilibrium is disturbed, presenting negative and positive electricity when deficient and when redundant. Others have plausibly argued for the presence of two fluids, distinct from each other. Others have considered the effects as referable to peculiar exertions of the attractive powers of matter, and have regarded the existence of any distinct fluid or form of matter to be as unnecessary to the explanation of the phenomena, as it is in the question concerning the cause of gravitation.

Supposed Cause of Electrical Phenomena.

When the flame of a candle is placed between a positive and negative surface, it is urged towards the latter; a circumstance which has been explained upon the supposition of a current of electrical matter passing from the positive to the negative pole;—indeed, it has been considered as demonstrating the existence of such a current of matter.* But if the flame of phosphorus be substituted for that of a candle, it takes an opposite direction; and, instead of being attracted towards the negative, it bends to the positive surface. It has been shown that inflammable bodies are always attracted by negative surfaces, and acid bodies, and those in which the supporters of combustion prevail are attracted by positive surfaces. Hence the flame of the candle throwing off carbon, is directed to the negative pole, while that of phosphorus goes to the positive, consistently with the ordinary laws of electro-chemical attraction.

There are many experiments which sanction the idea that electricity is “an exhibition of attractive powers acting in certain combinations.” If we discharge a Leyden phial through a quire of paper, the perforation is equally burred upon both sides, and not

Chemistry. upon the negative side only, as would have been the case if any material body had gone through in that direction. The power seems to have come from the centre of the paper, as if one-half of the quire had been attracted by the positive, and the other by the negative surface.

In this outline of the history of the powers of matter, an attempt has been made to draw together, under one point of view, the principal facts required to render the subsequent parts of this article intelligible. It has been necessary, on many occasions, to refer to the more extended discussions in the body of this work; and, under the heads CRYSTALLIZATION, CHEMICAL AFFINITY, HEAT, ELECTRICITY, and GALVANISM, the reader will find ample materials for the completion of this sketch.

PART II.

Of the substances belonging to our globe, some are of so subtle a nature as to require minute and delicate investigation to demonstrate their existence; they can neither be confined nor submitted to the usual modes of examination; and are known only in their states of motion as acting upon our senses, or as producing changes in the more gross forms of matter. They have been included under the general term of ETHERIAL or IMPONDERABLE MATTER, which, as it produces different phenomena, must be considered as differing either in its nature or affections. Respecting the nature of these phenomena, two opinions have been entertained, and each ably supported. It has been supposed by Huygens and Descartes, that they arise from vibrations of a rare elastic medium which fills space; while Newton has considered them as resulting from emanations of particles of matter.

The other forms of matter are tangible and ponderable, and, therefore, easily susceptible of accurate examination; they may be considered as resulting from the mutual agencies of heat and attraction, and are comprehended under the three classes of Solids, Liquids, and Gases.

RADIANT MATTER.

Properties
of the Solar
Rays.

In considering the phenomena of radiant matter as connected with chemistry, its mechanical properties must often be necessarily dwelt upon, as importantly connected with the changes it effects in the composition of bodies. These, however, cannot be minutely entered into in this place; they will be found discussed in the body of the work. (See OPTICS, &c.) Such points of the inquiry will only be alluded to as are absolutely necessary to render the subject intelligible to the Chemist. That a sun-beam, in passing through a dense medium, gives rise to a series of brilliant tints similar to those of the rainbow, was known in the earliest ages, but it required the sagacity of Newton to develop the cause of the phenomenon. He proved, that light consists of rays differing from each other, in their relative re-

Chemistry. frangibilities; and guided by their colour,—considered their number as seven:—red, orange, yellow, green, blue, indigo, and violet. Of these rays, the red being least refrangible, falls nearest that spot which the ray would have passed to, had it not been refracted, while the violet ray being most refrangible, is thrown to the greatest distance,—the intermediate rays possess mean degrees of refrangibility. These differently coloured rays are not susceptible of further decomposition, by any number of refractions, but when they are collected into a focus they reproduce white light. Upon these phenomena is founded the Newtonian theory of colours.

If a solar beam be refracted by a prism, and the coloured image received upon a sheet of paper, it will be found, on moving the hand gently through it, that there is an evident increase of temperature towards the red ray. This fact seems to have been first noticed by Dr Hutton (*Dissertation on Light and Heat*, p. 39); but it is to Dr Herschel (*Philos. Trans.* 1800) that we are indebted for a full investigation of the subject. If the coloured rays be thrown successively upon delicate thermometers, it will be found, that if the heating power of the violet rays be considered = 16, that of the green rays will be = 26, and of the red = 55. These circumstances suggested the possibility of the heating power of the spectrum extending beyond the red ray; and on applying a thermometer just out of the red ray, and beyond the limits of the visible spectrum, this was found to be the case. A thermometer in the red ray rose 7° in ten minutes, but just beyond the red ray the rise was = 9°. It is evident, therefore, that, independent of the illuminating rays, there are others which produce increase of temperature, and these, from their increase towards the red ray, and from the spot which they principally occupy in the refracted congeries, are possessed of less refrangibility than the visible rays.

That these calorific rays are susceptible of refraction and reflection, is proved by the intense heat produced when the solar rays are concentrated into a focus by a lens, or by a concave mirror.

The radiant matter emitted by terrestrial bodies at high temperatures, agrees in many of its properties with that constituting the solar rays, but in others it presents material differences. The investigation of this subject constitutes a beautiful department of philosophic inquiry. The effect we perceive in approaching a fire chiefly results from radiation; and is little connected with the immediate conducting power of the air: and if a concave metallic mirror be held opposite the fire, a heating and luminous focus will be obtained. The affections of terrestrial radiant matter are best demonstrated by employing two concave mirrors of planished tin or plated copper, placed at a distance of about 10 feet asunder. (*Pictet Essais de Physique*.) Under these circumstances, when a thermometer is in the focus of one of the mirrors, it will be found sensible to the effects of a heated body placed in the focus of the opposed mirror; and that the effect is produced by reflection, and not by mere direct radiation, is proved, either by drawing the thermometer out of the focus to-

Chemistry. wards the opposed mirror, or by placing a screen between the thermometer and its mirror, when diminution of temperature is in either case indicated.

If the flame of a candle be placed in the focus of one mirror, a heating and luminous focus is obtained from the other: but if a plate of glass be now interposed between the two mirrors, the rays of heat are arrested, while those of light freely passing through the glass, are collected, as usual, in the opposite focus. This, therefore, proves a difference between solar and terrestrial heat; the rays of the former pass through glass without heating it; the rays of the latter are stopped by glass, and it becomes hot when opposed to them. (Scheele's *Experiments on Air and Fire*.)

In these experiments upon the radiation of terrestrial heat, the temperature excited by the radiant matter appears always relative to that of the heated or radiating body; and if we assume that all bodies are constantly throwing off radiant matter, the effects of temperature which it produced when condensed or collected into a focus by a concave mirror will bear a relation to the source; for the particles may be conceived to move with such velocity as not to be affected by circumjacent bodies, or by the circumambient air. Thus, white hot iron produces a greater effect upon the focal thermometer than that which is only red hot, and red hot iron causes a greater effect than hot water—a body of the same temperature, as the thermometer causes no change in it, but cold bodies produce an effect of cold, because the particles which they radiate, when stopped impinging upon the thermometer bulb, are of a lower temperature. Radiation has by some been applied for upon the idea of the heated body producing undulations in the air, something analogous to waves excited by sonorous bodies; but in motion may rather be regarded as the cause of the effect, and the different phenomena of refraction and of solar and terrestrial radiation only be explained upon such an hypothesis. This opinion goes on in all elastic media, and in the æthereal and air pump vacuum.

Absorbing and Reflecting Powers of different Colours and Surfaces.

It has long been known in regard to solar rays, that their heating effect depends much upon the colour of the surfaces upon which they impinge, and that black and dark bodies are more heated than those which are white or of light tints, circumstances dependent upon absorption and reflection. Professor Leslie has shown that the phenomena of terrestrial radiation are connected with the nature of the radiating surface; and that those surfaces which are the best radiators of this heat, are also gifted with the greatest absorbing power. (Leslie on Heat.)

Unmetallic and unpolished surfaces are the best radiators, and also the best receivers of radiant heat; while polished metallic substances are the worst radiators, and have the lowest absorbing powers. In the experiments with the metallic mirrors, the whole nearly of the heat is reflected, and the mirror itself does not become warm; but if it be coated with any unpolished and especially unmetallic coating, as with paper, or paint, the radiation is then scarcely perceptible, and the mirror becomes hot from the absorption of the radiant matter.

In Professor Leslie's experiments it was found, that a clean metallic surface produced an effect = 12 upon the thermometer. When covered with a thin coat of glue, its radiating power was so far increased as to produce an effect = 80; and, on covering it with lamp-black, it became = 100.

In these cases of radiation the colour of the surface does not interfere, and the different effects must be referred to the mechanical structure of the radiating surface. White paper and lamp-black produce nearly the same effects, and paper coloured blue, red, yellow, and green, does not differ in radiating power from that which is white, provided the colour produces no change of texture in the paper.

The connection of the receptive with the radiating power is made obvious by coating the bulbs of thermometers with different substances. Thus, the effect of radiant heat upon a thermometer bulb covered with a thin coating of lamp-black being = 100; when the bulb is covered with silver-leaf the effect is only = 12.

Radiant matter possesses considerable influence over the chemical energies of bodies. If equal volumes of the gases called chlorine and hydrogen be exposed in a dark room, they slowly combine, and produce muriatic acid gas; but if they be exposed to the direct rays of the sun, the combination is very rapid, and often accompanied by an explosion.

Chlorine and carbonic oxide have scarcely any tendency to combine even at high temperature when light is excluded, but exposed to the solar rays they enter into chemical union. Chlorine has little action upon water, unless exposed to light, and, in that case, the water which consists of oxygen and hydrogen is decomposed. The hydrogen unites with the chlorine to produce muriatic acid, and the oxygen is evolved and combined in a gaseous form.

These, and numerous other similar cases which might be adduced, show that radiant matter influences the chemical energies of bodies, independent of its heating powers. Scheele (*Experiments on Air and Fire*, p. 78, &c.) was the first who entered upon this curious investigation; and many important facts connected with it have been more lately ascertained by Ritter, Wollaston, and Davy. Scheele threw the prismatic spectrum upon a sheet of paper, moistened with a solution of nitrate of silver, a salt quickly decomposed by the agency of light. In the blue and violet rays the silver was soon reduced, producing a blackness upon the paper, but in the red ray scarcely any similar effect was observed. Wollaston and Ritter discovered that these chemical changes were most rapidly effected in the space which bounds the violet ray, and which is out of the visible spectrum.

It has thus been ascertained, that the solar beams are refrangible into three distinct kinds of rays,—the calorific, or heating rays; the colorific rays which produce colour; the decomposing rays, or those which have a tendency to interfere with the chemical constitution of bodies.

In the prismatic spectrum these three sets of rays are imperfectly separated, and arranged according to their respective refrangibilities. The heating rays are the least refrangible, the colorific rays are pos-

Chemistry. **Chemistry.** ~~assessed~~ of more refrangibility, and the chemical, or, as some have called them, the deoxidizing rays, are the most refrangible.

Sir H. Davy has observed, that certain metallic oxides, when exposed, to the violet extremity of the prismatic spectrum, undergo a change similar to that which would have been produced by exposure to a current of hydrogen; and that, when exposed to the red rays, they acquire a tendency to absorb oxygen. (*Elements of Chemical Philosophy.*) In such general facts, he traces an analogy between the effects of the solar beam, and the agencies of electricity. In the Voltaic circuit, the maximum of heat is at the positive pole, where the power of combining with oxygen is also given to bodies; the agency of rendering bodies inflammable is exerted at the opposite surface, and similar chemical effects are produced by negative electricity, and by the most refrangible rays, and by positive electricity, and the rays which are least refrangible.

PART III.

Having thus rapidly explained the laws of Attraction, Heat, and Electricity, and the phenomena exhibited by Radiant Matter, we proceed to the Elementary or Undecomposed Bodies and their mutual combinations. These bodies are between fifty and sixty in number; four are gaseous, and the remainder solids: there are no simple liquids. They may be arranged under three heads:

1. Acidifying Supporters of Combustion.
2. Acidifiable Combustibles.
3. Metals.

The first division includes three substances.

1. Oxygen.
2. Chlorine.
3. Iodine.

1. **Oxygen.** (From *oxus* γένεσις, producer of acids.)

This elementary gaseous body may be obtained by heating to redness, in a glass retort, the salt called Oxymuriate of Potash, 100 grains of which yield about 100 cubical inches; it may be collected over water in the hydro-pneumatic apparatus. (See CHEMISTRY, *Encycl.*) It is also given off from black oxide of manganese, red oxide of lead, or nitre when exposed to a red heat. It was discovered by Dr Priestley in the year 1774. (Priestley on Air, Vol. II. 154.)

Oxygen gas is insipid, colourless, and inodorous; its specific gravity is 15, hydrogen being assumed = 1. 100 cubical inches at mean temperature and pressure weigh 33.75 grains. It is a powerful supporter of respiration and combustion. A small animal confined in oxygen gas, lives thrice as long as when confined in the same bulk of common air. A lighted taper, or a burning piece of sulphur, or phosphorus introduced into this gas, is very rapidly consumed, with intense ignition.

The phenomena of combustion were referred by

Stahl and his associates, to a peculiar principle **Chemistry.** which they called *phlogiston*: it was supposed to exist in all combustibles, and combustion was said to depend upon its separation; but this explanation was absurdly at variance with the well known fact, that bodies during combustion increase in weight.

After the discovery of oxygen gas, it was adopted by Lavoisier as the universal supporter of combustion. The basis of the gas was supposed to unite to the combustible, and the heat and light which it before contained in the gaseous state, were said to be evolved in the form of flame. But in this case, several requisites were not fulfilled; the light depends upon the combustible, and not upon the quantity of oxygen consumed; and there are very numerous instances of combustion in which oxygen, instead of being solidified, becomes gaseous during the operation; and, lastly, in others, no oxygen whatever is present. Combustion, therefore, cannot be regarded as dependent upon any peculiar principle or form of matter, but must be considered as a general result of intense chemical action. It may be connected with the electrical energies of bodies; for all bodies which powerfully act upon each other, are in the opposite electrical states of positive and negative; and the evolution of heat and light may depend upon the annihilation of these opposite states, which happens whenever they combine.

2. **Chlorine.** (From *χλωρος*, greenish yellow.)

To obtain this gas, a mixture of black oxide of manganese and muriatic acid may be heated over a lamp in a glass retort. It is soon copiously evolved, and may be conveniently collected over warm water; as it is absorbed by cold water, it cannot be long retained over that fluid.

It may also be procured in the same way from a mixture of 8 parts of common salt, 3 of black oxide of manganese, 4 of water, and 5 of sulphuric acid.

Chlorine was discovered by Scheele in 1774; it was called by him dephlogisticated muriatic acid. The term oxymuriatic acid was afterwards applied to it by the French chemists.

Chlorine is a permanently elastic gaseous fluid; it has a pungent and disagreeable smell, and is highly injurious when respired, even largely diluted with atmospheric air. Its colour is greenish yellow.

The specific gravity of chlorine, composed with hydrogen, is as 33.5 to 1; 101 cubic inches weigh 75.375 grains. At the temperature of 60°, water dissolves two volumes of chlorine. The solution is of a pale yellow colour, has an astringent nauseous taste, and destroys vegetable colours, though the gas itself, when perfectly free from moisture, has scarcely any action upon them. When a burning taper is immersed in a jar of chlorine, the brilliancy of the flame is much impaired, it becomes red, throws off much charcoal, and is soon extinguished. Many bodies, such as phosphorus and several of the metals, are spontaneously ignited by chlorine, and burn in it with much brilliancy. In these cases, binary compounds result, some of which, like those of oxygen, are possessed of acid properties. Others are not acid, and

Chemistry. such compounds with oxygen, being called *oxides*, those which chlorine forms may be termed *chlorides*. *

Chlorine was once regarded as composed of oxygen and muriatic acid, a fallacy arising from the presence of water, and which will be rendered more intelligible under the head *Muriatic Acid*. (See Davy's Paper, *Phil. Trans.* 1811.)

Chlorine and oxygen unite in two proportions, forming an oxide and an acid.

Oxide of Chlorine or *Euchlorine*, so called by its discoverer, Sir H. Davy (*Phil. Trans.* 1815), from its very deep colour, may be obtained as follows. Upon 10 or 12 grains of the salt called oxymuriate of potash, drop a small quantity of sulphuric acid, and stir the mixture with a platinum knife, having so adjusted the relative quantities of salt and acid, that they may form together a yellow powder. Put this into a very small retort or bent tube, and by a water bath, apply a temperature of 150°. *Euchlorine* will pass off, and may be collected over quicksilver in small jars, or tubes. The smell of this gas somewhat resembles that of chlorine, but is much less irritating and disagreeable. Its taste is astringent, and not at all acid. When gently heated, it is decomposed with explosion and expansion,—two volumes are enlarged into three, of which two consist of oxygen, and one of chlorine; it is therefore composed of 33,5 parts by weight of chlorine combined with 30 of oxygen.

Chloric acid. In the compound which has been thus called by its discoverer M. Gay-Lussac (*Annales de Chimie*, tom. 91, p. 108), the relative proportions of chlorine to oxygen are to each other as 33,5 to 37,5; but it is a compound which cannot exist, independent of water or some base, and, therefore, may be compared to the *sulphuric acid*. It may be prepared by passing a current of chlorine, through a mixture of oxide of silver † and water. Chloride of silver is produced, which is insoluble, and may be separated by filtration. The excess of chlorine which the filtered liquor contains is separable by heat, and the chloric acid dissolved in water remains. It is a sour colourless liquid, producing peculiar compounds afterwards to be described. It forms no precipitate in any metallic solution. Its compounds may be called *chlorates*. The most remarkable of them have been long known under the name of *Oxymuriates*.

3. Iodine. (From *ιώδης*, violaceous.)

Iodine is procured by the following process: Lixivate powdered kelp with cold water. Evaporate the lixivium till a pellicle forms, and set aside to crystallize. Evaporate the mother liquor nearly to dryness, and pour upon the mass half its weight of sulphuric acid. Apply a gentle heat to this mixture in a glass alembic; fumes of a violet colour arise and

condense in the form of opaque crystals, having a *Chemistry.* metallic lustre.

This body was discovered in 1812 by M. Courtois of Paris. Vauquelin (*Annales de Chimie*, t. 90), Gay-Lussac (*ib.* 91), and Davy (*Phil. Trans.* 1814), have successfully investigated its properties.

Iodine has a bluish black colour; its lustre is metallic. It is soft and friable. Its specific gravity = 4,946. It produces a yellow stain upon the skin. Its smell resembles that of diluted chlorine; its taste acid. It is extremely volatile, and, at a temperature between 60° and 80°, produces a violet vapour. At 120° or 130° it rises more rapidly. At 220° it fuses, and produces copious violet-coloured fumes, which condense in brilliant plates, and acute octoedrons. Like chlorine and oxygen, it is electro-negative; and therefore attracted by the positive surface of the Voltaic pile.

Oxiiodic acid (Davy, *Phil. Trans.* 1815). This compound of oxygen and iodine cannot be obtained directly, for those bodies exert no mutual action. It is procured by acting upon *euchlorine* by iodine. A liquid is formed, which consists of chloriiodic and oxiiodic acids. The former is separable by a gentle heat, the latter remains as a white, semitransparent, sour, and inodorous body, very soluble in water. It consists of 117 iodine, 37,5 oxygen.

Chloriiodic acid is easily obtained by the direct action of chlorine upon iodine. They unite and form crystals of a deep orange colour, deliquescent, and easily fusible and soluble. The solution is sour. This compound contains 117 iodine, 33,5 chlorine.

The second division of undecomposed substances includes those which are acidifiable and combustible. These are,

1. Hydrogen.
2. Nitrogen.
3. Sulphur.
4. Phosphorus.
5. Carbon.
6. Boron.

1. Hydrogen. (From *υδρογ.*, &c. the base of water.)

Hydrogen was first duly examined by Mr Cavendish (*Phil. Trans.* Vol. 56). It is obtained by acting upon dilute sulphuric acid by zinc filings, and by other methods presently to be noticed.

It is an æriform fluid, not absorbable by water. It has no taste, a slightly disagreeable smell, and may be respired for a short time, though it is instantly fatal to small animals. It is the lightest body known; and we therefore conveniently assume it as unity in speaking of the specific gravity of gases, as well as in referring to the proportions in which bodies combine. 100 cubic inches weigh at mean temperature and pressure 2,25 grains. It is inflamma-

* Sir H. Davy designates these compounds by the terminations *ane* and *ana*.

† Prepared by precipitating the solution of nitrate of silver with lime-water.

Chemistry. ble, and extinguishes flame. When pure, it burns quietly with a lambent blue flame at the surface in contact with air, but if mixed with thrice its volume of air, it burns rapidly, and with detonation.

Hydrogen and Oxygen.—When two volumes of hydrogen gas are mixed with one volume of oxygen gas, and the mixture inflamed in a proper apparatus by the electric spark, the gases totally disappear, and the interior of the vessel is covered with drops of pure water, equal in weight to that of the gases consumed.

If pure water be exposed to the action of Voltaic electricity, it is resolved into two volumes of hydrogen, disengaged at the negative pole, and one volume of oxygen, disengaged at the positive pole; so that water is thus proved by synthesis, and by analysis, to consist of two volumes of hydrogen, combined with one volume of oxygen. The specific gravity of hydrogen compared with oxygen, is as 1 to 15; therefore the component parts of water by weight are,

1 hydrogen,
7,5 oxygen.

Representative }
number of water } = 8.5

or thus,

H.	O.	
1	7,5	water
		8,5.

The mechanical and other properties of water are discussed at length in the body of the work. Its composition was discovered by Mr Cavendish in 1781.

Hydrogen and Chlorine.—When equal volumes of these gases are mixed, and exposed to light, they combine, and produce a sour compound, commonly called *muratic acid gas*; or, in conformity to more modern nomenclature, *hydrochloric acid gas*. The best mode of showing the composition of *muratic acid*, is to introduce into a small but strong glass vessel a mixture of the two gases, and to inflame them by the electric spark; no change of volume ensues, and *muratic acid* results. This compound may be decomposed by the action of several of the metals. Potassium, for instance, absorbs the chlorine, and the hydrogen is evolved; and *muratic acid* gas thus affords half its volume of hydrogen. As the specific gravity of hydrogen to chlorine is as 1 to 33,5, *muratic acid* will consist of 1 hydrogen + 33,5 chlorine, and its representative number will be 34,5.

H.	C.	
1	33,5	Muratic Acid.
		34,5

Chemistry. *Muratic acid* may also be readily procured by acting upon common salt by sulphuric acid, the evolved gas must be received over mercury. It was first obtained pure by Dr Priestley, but its composition was discovered by Scheele, and has since been most ably investigated by Davy. *Muratic acid* gas extinguishes flame; it is sour and acrid. Its specific gravity, compared with hydrogen, is = 17,25 to 1. 100 cubic inches = 39,5 grains. It is greedily absorbed by water, which takes up 480 times its bulk, and has its specific gravity increased from 1 to 1,210. Thus dissolved in water, it forms the liquid *muratic acid* or spirit of salt, and may easily be procured by distilling a mixture of dilute sulphuric acid and common salt.

Hydrogen and Iodine exert a slow action under ordinary circumstances; but when iodine is presented to nascent hydrogen, they readily unite, and produce a gaseous acid, the *hydriodic acid*. It is prepared by the action of moist iodine upon phosphorus, and must be received over mercury. It is colourless, very sour, and smells like *muratic acid*. Its specific gravity to hydrogen is as 60,7 to 1. It is instantly decomposed by chlorine, which produces *muratic acid*, and the blue vapour of iodine is rendered evident.

It consists of - - - 1 hydrogen,
117 iodine,

Hydriodic acid = 118

2. Nitrogen. (i. e. produce of nitric acid.)

This was first recognised as a distinct æriform fluid by Dr Rutherford in 1772. (Thesis, *De ære Mcphitico*.) It may be obtained by heating phosphorus in a confined portion of dry atmospheric air, which is a mixture of nitrogen and oxygen; the phosphorus absorbs the latter, and the former gas remains. After repeated washing with lime-water, it may be considered as pure.

100 cubic inches weigh 29,25 grains; so that its specific gravity, compared with hydrogen, is as 13 to 1. It is tasteless, inodorous, and insoluble in water. It does not support combustion, and is fatal to animals; hence was called *azote*. It is not inflammable; but when its compounds are submitted to Voltaic decomposition, it is attracted by the negative pole.

Nitrogen and Oxygen.—These bodies unite in four proportions, and form the compounds called,

1. Nitrous oxide.
2. Nitric oxide.
3. Nitrous acid.
4. Nitric acid.

Nitrous oxide may be obtained by distilling nitrate of ammonia at a temperature of about 420°. The gas which passes off may be collected over water, and is *nitrous oxide*. 100 cubic inches weigh 46,125 grains; its specific gravity, therefore, to hydrogen is as 20,5 to 1. The taste of this gas is sweet, and its smell peculiar, but agreeable. Its singular effects resembling intoxication when respired, were first ascertained by Sir H. Davy. It supports combus-

Chemistry. tion. It is easily absorbed by water, which takes up about its own bulk.

The best analysis of this gas is effected by detonation with hydrogen; one volume of nitrous oxide requires one volume of hydrogen. This mixture, fired by the electric spark, produces water, and one volume of nitrogen remains. Now, as one volume of hydrogen takes one-half volume of oxygen to form water, nitrous oxide must consist of two volumes of nitrogen and one volume of oxygen; these three volumes being so condensed in consequence of chemical union, as only to fill the space of two volumes. The specific gravity of nitrogen, compared with oxygen, is as 13 to 15; nitrous oxide, therefore, consists of

	13	Nitrogen.
	7,5	Oxygen.
Number for nitrous oxide,	20,5	

Nitrogen.	Oxygen.		Nitrous oxide.
13	7,5	=	20,5

Nitric Oxide is usually obtained by presenting certain substances to nitric acid, which abstract a portion of its oxygen, leaving the remaining element in such proportion as to constitute the gas in question; for this purpose, some copper filings may be put into a gas bottle with nitric acid diluted with thrice its bulk of water; an action ensues, red fumes are produced, and there is a copious evolution of the gas, which may be collected and preserved over water. This gas is presently recognised by the red fumes which it produces when brought into the contact of air.

It extinguishes most burning bodies, but phosphorus readily burns in it. Its specific gravity to hydrogen is as 14 to 1. 100 cubic inches weigh = 31.5 grains.

It does not detonate when mixed with oxygen, and subjected to the electric spark; but it may be decomposed by the action of some of the metals at high temperatures, which absorb its oxygen. One volume of nitric oxide is thus resolved into equal volumes of oxygen and nitrogen. If, therefore, we call nitrous oxide a compound of 1 proportion of nitrogen + 1 oxygen, then nitric oxide may be considered as consisting of 1 nitrogen + 2 oxygen, or by weight, 13 nitrogen + 15 oxygen, and its symbol will stand thus:

Nitrogen.	Oxygen.		Nitric oxide.
13	7,5		28.

Nitrous Acid Gas.—When nitric oxide is presented to oxygen, the two gases combine, and a new gaseous compound of a deep orange colour results. This compound is not easily examined, because it is absorbed both by quicksilver and water, so that we are obliged to resort to exhausted glass vessels for its production. When we thus mix two volumes of

VOL. III. PART I.

Chemistry. nitric oxide with one volume of oxygen, the gases become condensed to about half their original volumes, and form nitrous acid gas. This gas supports the combustion of the taper, of phosphorus, and of charcoal, but extinguishes sulphur. It is readily absorbed by water, forming a green sour liquid. Its specific gravity to hydrogen is as 28.6 to 1, and 100 cubic inches = 64.48 grains.

It is obvious that this nitrous acid gas must consist of 13 nitrogen + 30 oxygen, and, therefore, its number is 43, for nitric oxide is composed of equal volumes of nitrogen and oxygen, and one additional volume of oxygen, or two proportions by weight are added to form nitrous acid.

Nitrogen.	Oxygen.	
13	7,5	
	7,5	
	7,5	
	7,5	>30

Nitric Acid.—The fourth compound of nitrogen with oxygen is the nitric acid; the nature of which was first demonstrated by Mr Cavendish in 1785. (*Phil. Trans.*) It is usually obtained from nitre, three parts of which are distilled with two of sulphuric acid.

The nitric acid is a colourless liquid, extremely sour and corrosive. Its specific gravity is 1.42; it always contains water, which modifies its specific gravity. At 250° it boils and distils over without change. At 40° it congeals. It absorbs water from the air, and its bulk is thus increased, while its specific gravity is diminished. It is usually coloured by nitrous acid gas.

Nitric acid in its dry state, that is, as it exists combined with metallic oxides, may be regarded as composed of one proportion of nitrogen = 13, and 5 of oxygen = 37,5, and this will be the symbol representing its composition.

Nitrogen.	Oxygen.	
13	7,5	
	7,5	
	7,5	
	7,5	
	7,5	} 37,5

Consequently, the representative number of *dry* nitric acid is 50.5. But in its liquid state it always contains water, and when, in this state, its specific gravity is 1.5, it may be regarded as a compound of one proportion of dry acid and two of water, and this may be numerically expressed thus:

Acid.	Water.	
50,5	17	= 67,5 liquid acid.
		spe. grav. 1,5.

Nitromuriatic Acid.—This term has been applied to the *Aqua Regia* of the alchemists. When nitric and muriatic acids are mixed, they become yellow, and acquire the power of readily dissolving gold, which neither of the acids possessed separately. This mixture evolves chlorine, a partial decomposition of both acids having taken place, and water, chlorine, and nitrous acid

Chemistry. gas, are thus produced; that is, the hydrogen of the muriatic acid abstracts oxygen from the nitric to form water. The result must be chlorine and nitrous acid. (Davy, *Journal of Sciences and the Arts*, Vol. I. p. 67.)

Nitrogen and Chlorine.—These gases do not unite directly, but the compound may be obtained by exposing a solution of nitrate or muriate of ammonia to the action of chlorine, at a temperature of 60° or 70°. The gas is absorbed, and an oil-like fluid, heavier than water, is produced. It was discovered by M. Dulong. (*Annales de Chimie*, Vol. LXXXV.) Its specific gravity is 1,6; it is not congealed by cold. This substance is dangerously explosive, and is decomposed with violent detonation by many combustibles, especially phosphorus, and fixed oils. Alcohol quietly changes it into a white substance: Mercury absorbs the chlorine, and evolves nitrogen. It yields, by decomposition, 1 volume of nitrogen and 4 of chlorine; and as the specific gravity of nitrogen to chlorine is as 13 to 33,5, so it may be said to consist of 1 proportion of nitrogen + 4 proportions of chlorine, or 13 + 134 by weight, and its number will be 147.

Nitrogen.	Chlorine.
13	33,5
	33,5
	33,5
	33,5

} 134

Nitrogen and Iodine.—A compound of these bodies may be procured by pouring a solution of ammonia upon a very small quantity of iodine. Hydriodic acid is one product, and the other a brown powder, which detonates upon the slightest touch, and is resolved into nitrogen and iodine.

Nitrogen and Hydrogen—Ammonia or Volatile Alkali.—This gaseous compound may be obtained by heating a mixture of quicklime and muriate of ammonia. It must be collected over mercury. It is a permanently elastic gas at common temperatures, extremely pungent and acrid, but when diluted by mixture with common air, agreeably stimulant. It converts most vegetable blues to green, and the yellows to red, properties which belong to the bodies called alcalies. Ammonia, therefore, has been termed volatile alkali.

Its specific gravity to hydrogen is as 8 to 1—100 cubical inches weighing 18 grains. It extinguishes flame, but forms an inflammable mixture with common air and with oxygen.

Water at the temperature of 50° takes up 670 times its volume of ammonia; its bulk is increased, and specific gravity diminished; that of a saturated solution is 0,875, water being 1,000. Ammonia may be decomposed by detonation with oxygen; also by passing it through a red hot iron tube. It yields one volume of nitrogen and three of hydrogen, and therefore consists by weight of 13 nitrogen + 3 hydrogen, and its representative number is 16.

Ammonia and Chlorine.—When these gases are mixed, a partial decomposition of the former ensues. On mixing 15 parts of chlorine and 40 of ammonia, heat and light are evolved; 5 parts of nitrogen are liberated, and muriate of ammonia is formed.

Ammonia and Muriatic Acid—Muriate of Ammonia—Sal Ammoniac.—This salt may be produced directly by mixing equal volumes of ammonia and muriatic acid, when an entire condensation ensues.

The specific gravity of ammonia to muriatic acid is as 16. to 34,5, therefore, muriate of ammonia consists of 34,5 muriatic acid + 16 ammonia.

Ammo.	Mur. Acid.
16	34,5

Ammonia and Nitric Acid—Nitrate of Ammonia.—This salt may be procured by the direct union of ammonia with nitric acid—or more easily by saturating dilute nitric acid with carbonate of ammonia. It has been mentioned as the source of nitrous oxide, and when heated is entirely resolved into that gas and water. It consists of one proportion of nitric acid = 50,5 + one proportion of ammonia = 16, and therefore the representative number of the nitrate of ammonia is 66,5. Or it may be considered as containing 2 proportions of nitrogen, 3 of hydrogen, and 5 of oxygen, as the following symbols show:

Nitric Acid.

Nitrogen.	Oxygen.
13	7,5
	7,5
	7,5
	7,5
	7,5

37,5 + 50,5

Acid. Ammo. Nitrat. of
50,5 + 16 = 66,5.

Ammonia.

Nitrogen.	Hydrog.
13	1
	1
	1

3 = 16.

Nitrous oxide consists of 1 proportion of nitrogen = 13 + 1 of oxygen = 7,5; hence the two proportions of nitrogen in the salt (1 in the acid and 1 in the ammonia) will require two of oxygen to produce nitrous oxide, and the remaining 3 of oxygen will

Chemistry. unite to the 3 of hydrogen, and form water. And accordingly nitrous oxide and water are the only possible results; so that the elements, after the decomposition of the salt, are arranged thus:

Nitrogen.	Oxygen.
13	7,5
Nitrogen.	Oxygen.
13	7,5

= Nitrous oxide.

Hydrog.	Oxygen.
1	7,5
Hydrog.	Oxygen.
1	7,5
Hydrog.	Oxygen.
1	7,5

= Water.

Atmospheric Air may be considered as a mixture of 21 per cent. of oxygen with 79 of nitrogen; 100 cubical inches at mean pressure and temperature weigh 30,195 grains, and its specific gravity compared with hydrogen is as 13,42 to 1.

3. Sulphur.

A substance of a pale yellow colour, insipid and inodorous, but exhaling a peculiar smell when heated. Its specific gravity is 1,990. It is principally a mineral product, and occurs crystallized, its primitive form being a very acute octoëdron, with an oblique base. When sulphur is heated to about 180° it volatilizes, and its peculiar odour is strong and disagreeable; at 225° it liquefies; between 350° and 400° it becomes viscid, and of a deep brown colour; and at about 600° it quickly sublimes. When slowly cooled after fusion, it forms a fibrous crystalline mass.

Sulphur forms compounds with oxygen, chlorine, iodine, and hydrogen.

Sulphur and Oxygen.—To oxygen it unites in two proportions, giving rise to the compounds, sulphurous and sulphuric acid. *Sulphurous acid*, or, as it should rather be called, *sulphurous oxide*, is a gaseous body, which may be obtained by several processes. It may be procured directly by burning sulphur in oxygen gas, or indirectly by heating mercury in sulphuric acid. It must be collected and preserved over mercury, for water takes up rather more than 30 times its bulk of this gas, forming the liquid sulphurous acid, which, when recently prepared, has a sulphureous astringent taste, and destroys many vegetable colours; but by keeping it acquires a sour

flavour, and reddens the generality of vegetable blues. If sulphur be burned in oxygen, sulphurous acid is produced, without any change in the volume of the gas, so that its composition is easily learned by the increase of weight; and as 100 cubic inches of oxygen (weighing 33,75 grains) dissolve 83,75 grains of sulphur, it is obvious that the sulphurous acid is composed of equal weights of sulphur and oxygen; and if we regard it as consisting of two proportions of oxygen and one of sulphur, the latter element will be represented by the number 15; and the sulphurous acid, consisting of 1 proportion of sulphur = 15, and 2 proportions of oxygen = 15, will be represented by 30, which is also its relative specific gravity to hydrogen, considering the latter as = 1; 100 cubical inches of sulphurous acid gas weigh 67,5 grains. This gas has a suffocating nauseous odour, an astringent taste; it extinguishes flame, and kills animals. When mixed in equal volume with ammonia, a yellowish salt is produced, which is a sulphite of ammonia, and which consists of 60 sulphurous acid + 16 ammonia.

Sulphuric Acid.—This body was formerly obtained by the distillation of green vitriol, and called *oil of vitriol*. It is now procured in this country by burning a mixture of 8 parts of sulphur and 1 of nitre in close chambers containing water, by which the fumes produced are absorbed, and by evaporation the acid is procured in a more concentrated state.

Sulphuric acid, as usually met with, is a limpid colourless fluid, having a specific gravity of 1,85,—it boils at 620°, and freezes at 15°. It is very acrid and caustic, and when diluted with water, produces a very sour liquid. It rapidly absorbs water from the atmosphere, and upon sudden mixture with water produces much heat.

In sulphuric acid 1 proportion of sulphur = 15, is combined with 3 proportions of oxygen = 22,5, and, consequently, *dry* sulphuric acid is correctly represented by 15 + 22,5 = 37,5, but it only exists in this state (like the nitric and chloric acids) when united with bases, and in its ordinary state contains water, and should, therefore, be called *Hydrosulphuric Acid*. It has been found by experiment, that 100 parts of sulphuric acid, specific gravity 1,9, contain 18,2 of water, consequently, it may be looked upon as composed of 1 sulphur + 3 oxygen + 1 water:

or of 15 sulphur
 22,5 oxygen
 8,5 water

46 = number for liquid sulphuric acid.

The *formation* of sulphuric acid by the combustion of sulphur and nitre is as follows:

The sulphur, by burning in contact with atmospheric air, forms *sulphurous acid*. The nitre gives rise to the production of *nitric oxide*, which, with the oxygen of the air, produces *nitrous acid gas*. When these gases (*i. e.* sulphurous and nitrous acids) are *perfectly dry*, they do not act upon each other, but moisture being present in small quantity, they form a white solid, which is instantly decom-

Chemistry. posed when put into water; the nitrous acid reverts to the state of nitric oxide, having transferred one additional proportion of oxygen to the sulphurous acid, and, with water, producing the sulphuric acid; while the nitric oxide, by the action of the air, again affords nitrous acid, which plays the same part as before.

Sulphurous acid consists of

Sulphur.		} 15; and nitrous acid contains
15	Oxygen. 7,5	
	7,5	
Nitrogen.		} 30; hence every two portions of sulphurous acid require one of nitrous acid, which transfers two of oxygen, and passes back into the state of nitrous gas, sulphuric acid

	7,5		

The decomposition of sulphuric acid may be effected by passing it through a red hot platinum tube, when it is resolved into sulphurous acid, oxygen, and water. Its uses are numerous and important.

Sulphuric Acid and Ammonia—*Sulphate of Ammonia*—may be obtained by passing ammonia into sulphuric acid, but is usually prepared by saturating dilute sulphuric acid with carbonate of ammonia. By crystallization it affords six sided prisms. This salt is important as a source of the muriate of ammonia. It dissolves in twice its weight of water at 60°, and consists of 1 proportion of sulphuric acid = 37,5 + 1 proportion of ammonia = 16. Its number, therefore, is 53,5. When heated, ammonia is given off, and a *supersulphate* remains, consisting of 2 proportions of acid + 1 of alkali.

Sulphur and Chlorine—*Chloride of Sulphur*.—When sulphur is heated in chlorine, it absorbs rather more than twice its weight of that gas. 10 grains of sulphur absorb 30 cubic inches of chlorine, and produce a greenish-yellow liquid, consisting of 15 sulphur + 33,5 chlorine, and represented, therefore, by the number 48,5. It exhales suffocating and irritating fumes when exposed to the air. Its specific gravity = 1,6. It does not affect dry vegetable blues; but when water is present, instantly reddens them. Sulphur is deposited, and sulphureous, sulphuric, and muriatic acids are formed in consequence of a decomposition of the water.

Sulphur and iodine readily unite, and form a black crystallizable compound.

Sulphur and Hydrogen—*Sulphuretted Hydrogen Gas*.—This gaseous compound of sulphur and hydrogen was discovered by Scheele in 1777. It may be obtained by presenting sulphur to nascent hydrogen, which is the case when sulphuret of iron is acted upon by dilute sulphuric acid. This gas may be collected over water, though, by agitation, that fluid absorbs thrice its bulk. It has a fetid odour. Its specific gravity to hydrogen is as 16 to 1. 100 cubic inches = 36 grains. It extinguishes flame; and, when respired, proves fatal. It is very deleterious, even though largely diluted with atmospheric air. When one volume of sulphuretted hydrogen, and 1½ of oxygen, are inflamed in a detonating tube, 1 volume of sulphurous acid is produced, and water is formed. Thus the sulphur is transferred to one volume of the oxygen, and the hydrogen to the half volume. Sulphuretted hydrogen, therefore, consists of 15 sulphur + 1 hydrogen, and its number is 16.

Chlorine and iodine instantly decompose sulphuretted hydrogen; sulphur is deposited, and hydrochloric and hydriodic acids are formed.

Sulphuretted hydrogen and ammonia readily unite in equal volumes, and produce *hydrosulphuret of ammonia*. At first white fumes appear, which become yellow. A yellow crystallized compound results, consisting of 16 sulphuretted hydrogen, 8 ammonia.

Chemistry. It is of much use as a test for the metals, and may be procured by distilling, at nearly a red heat, a mixture of 6 parts of slacked lime, 2 of muriate of ammonia, and 1 of sulphur.

There is another compound of hydrogen and sulphur, which has been called supersulphuretted hydrogen. It is a liquid, formed by adding muriatic acid to a solution of sulphuret of potash, and appears to consist of two proportions of sulphur = 80 + one of hydrogen = 1.

Sulphur and nitrogen do not combine. Sulphur always, in its ordinary state, contains hydrogen, which it gives off during the action of various bodies, for which it has a powerful attraction.

4. Phosphorus

Is obtained by distilling phosphoric acid with charcoal at a red heat. When pure, it is nearly colourless, semitransparent, and flexible. Its specific gravity = 1,770. It melts, when air is excluded, at 105°. If suddenly cooled after having been heated to 140°, it becomes black; but if slowly cooled, remains colourless. At 500°, it boils, and rapidly evaporates. When exposed to air, it exhales luminous fumes, having a peculiar alliaceous odour; it is tasteless. At a temperature of about 100°, it takes fire, and burns with intense brilliancy, throwing off copious white fumes. If, instead of burning phosphorus with free access of air, it be heated in a confined portion of very rare air, it enters into less perfect combustion, and three compounds of phosphorus with oxygen are the result, each characterized by distinct properties. The first is a red solid, less fusible than phosphorus; the second is a white substance, more volatile than phosphorus; the third a white and fixed body.

The red solid consists of a mixture of phosphorus and oxide of phosphorus. *Oxide of phosphorus* is the white substance with which phosphorus becomes encrusted when kept for some time in water. It is very inflammable, and less fusible and volatile than phosphorus.

Phosphorous acid is best procured by mixing chloride of phosphorus with water, filtering and evaporating the solution, when a white crystallized solid is obtained, which is a compound of the phosphorous acid with water. (See *Chloride of Phosphorus*.)

The *phosphoric acid* may be produced by burning phosphorus in excess of oxygen. There is intense heat and light produced, and white deliquescent flocculi line the interior of the receiver. Phosphoric acid may also be obtained by acting upon phosphorus by nitric acid.

The composition of phosphoric acid is learned by ascertaining the bulk of oxygen absorbed during the perfect combustion of a given weight of phosphorus, which is = 4,4 cubic inches for each grain; so that 100 grains of phosphorus would require, for conversion into phosphoric acid, 440 cubic inches of oxygen = 148,5 grains. Hence phosphoric acid, considered as a compound of one proportion of phosphorus, and two proportions of oxygen, will consist of 10 phosphorus + 15 oxygen.

Phosphoric acid is a deliquescent substance: when fused it has been called Glacial Phosphoric

Chemistry. Acid. It is inodorous, very sour, fixed in the fire, and unchanged by heat. As commonly prepared, it is an unctuous fluid. Specific gravity = 2.

Phosphite of Ammonia may be obtained in delicate annular crystals, decomposable by heat.

Phosphate of Ammonia is a common ingredient in the urine of carnivorous animals. It may be obtained pure by saturating phosphoric acid with ammonia, and forms crystals in four-sided prisms.

Phosphorus and Chlorine.—These elements unite in two proportions, forming two definite compounds,—the chloride and bichloride of phosphorus. When phosphorus is submitted to the action of chlorine, it burns with a pale yellow flame, and produces a white volatile compound, which attaches itself to the interior of the vessel. This substance was long mistaken for phosphoric acid, but its volatility is alone sufficient distinction; it rises in vapour at 200°. It is fusible and crystallizable; and when brought into the contact of water, a mutual decomposition is effected, and phosphoric and muriatic acids result. When passed through a red-hot porcelain tube with oxygen, phosphoric acid is produced, and chlorine evolved.

With ammonia it forms a singular compound, which, though consisting of three volatile bodies, remains unchanged at a white heat,—it is insoluble in water.

When phosphorus is burned in chlorine, one grain absorbs nine cubic inches; so that the compound formed must be regarded as the *bichloride*, and consists of 10 of phosphorus + 67 of chlorine, and its number is 77.

The *Chloride of Phosphorus*, consisting of 10 phosphorus + 33,5 chlorine, is procured by distilling a mixture of phosphorus and corrosive sublimate, which is a bichloride of mercury. In this experiment calomel, or chloride of mercury, is formed, and the phosphorus combines with one proportion of chlorine.

The chloride of phosphorus, when first obtained, is a liquid of a reddish colour; it soon deposits a portion of phosphorus, however, and becomes limpid and colourless. Its specific gravity = 1,45. Exposed to the air it exhales acid fumes: it does not change the colour of dry vegetable blues. Chlorine converts it into bichloride. Ammonia separates phosphorus, and produces the singular triple compound before adverted to.

Chloride of phosphorus acts upon water with great energy, and produces muriatic and phosphorous acids, while the bichloride produces muriatic and phosphoric acids: for as in the bichloride there are two proportions of chlorine, so, in acting upon water, two of oxygen must be evolved, which, uniting to one of phosphorus, generate phosphoric acid. The chloride of phosphorus, on the contrary, containing only one proportion of chlorine, produces muriatic acid and phosphorous acid, when it decomposes water.

Before decomposition:

	Chlorid. of Phosp.		Water.
1 Chlorine = 33,5	} 43,5	1 Hydrog. = 1	} 8,5
1 Phospho. = 10		1 Oxygen = 7,5	

After decomposition.

	Muriatic Acid.		Phosph. Acid.
1 Chlorine = 33,5	} 36,5	1 Phospho. = 10	} 17,5
1 Hydrog. = 1		1 Oxygen = 7,5	

But the phosphorous acid thus produced always contains water, which it throws off when heated in ammonia, forming, with that alkali, a dry phosphite. This experiment shows that the *Hydrophosphorous acid* consists of 2 proportions of phosphorous acid = 35 + 1 water = 8,5.

Phosphorus and Iodine.—When these substances are brought together in an exhausted vessel, they act violently, and form a reddish compound, it decomposes water with great energy, and produces phosphorous and hydroiodic acids.

Phosphorus and Hydrogen.—When phosphorus is presented to nascent hydrogen, two gaseous compounds result. The one inflames spontaneously upon the contact of the atmosphere. This may be procured by heating phosphorus in a solution of caustic potash, or better, by acting upon phosphuret of lime by dilute muriatic acid. The gas may be collected over water. It is colourless, has a nauseous odour like onions, a very bitter taste, and inflames when mixed with air, a property which it loses by being kept over water. For our knowledge of the properties and composition of this gas we are chiefly indebted to Dr Thomson, who has shown that the hydrogen suffers no change of bulk in uniting to the phosphorus; so that the difference of weight between this gas and pure hydrogen indicates the weight of phosphorus: 100 cubic inches of phosphuretted hydrogen = 24,75 grains; hence the gas may be regarded as containing one proportion of phosphorus and one of hydrogen, or $10 + 1 = 11$.

The next compound of phosphorus and hydrogen has been called, by Sir H. Davy, *hydrophosphoric gas*. It is procured by heating the solid hydrophosphorous acid. The gas must be collected over mercury. Its specific gravity to hydrogen is as 12 to 1. It is not spontaneously inflammable, but explodes when heated with oxygen. It inflames spontaneously in chlorine. It smells less disagreeable than the former. It consists of 2 of hydrogen and 1 of phosphorus.

$2 + 10 = 12$; but the two volumes of hydrogen are condensed into one. 100 cubic inches weigh 27 grains.

When hydrophosphorous acid is decomposed for the production of this gas, phosphoric acid is always generated. Hydrophosphorous acid has been stated to contain two proportions of phosphorous acid + one of water. Hence the elements

20 phosphorus	} = phosphorous acid,
15 oxygen	
7,5 do.	
1 — hydrogen	= water,

or 43,5 parts of hydrophosphorous acid contain

20 phosphorus
22,5 oxygen
1 hydrogen.

The three proportions of oxygen = 22,5 will require one proportion and a half of phosphorus = 15 to form phosphoric acid, and the remaining half proportion of phosphorus will unite to the one of hydrogen to form hydrophosphoric gas, which consist of 5 phosphorus + 1 hydrogen.

To avoid fractions the phenomena may be stated thus:

Four proportions of hydrophosphoric acid contain

4 phosphorus	=	40.
4 oxygen	=	30.
2 do.	} in the	= 15.
2 hydrogen		
	water =	2.

The whole of the oxygen, amounting to 6 proportions (*i. e.* $7,5 \times 6 = 45$), unites to three proportions of phosphorus ($10 \times 3 = 30$) to form phosphoric acid. The two of hydrogen = 2, combine with the remaining proportion of phosphorus = 10 to form hydrophosphoric gas.

Phosphorus and Nitrogen produce no definite compound.

Phosphorus and Sulphur may be readily united by fusion in an exhausted vessel. When one proportion of phosphorus is united to one of sulphur ($10 + 15$), the compound bears a high temperature without decomposition.

5. Carbon.

The purest form of this element is the diamond, a colourless transparent body found in certain alluvial strata; its primitive crystalline form is the regular octoëdron. Its specific gravity = 3,50.

Another form of carbon is charcoal, and of this the purest variety is lamp-black. Charcoal is possessed of some very curious properties in regard to absorbing gases, and removing the colour, smell, and taste of certain vegetable and animal bodies.

Carbon and Oxygen.—There are two compounds of carbon and oxygen,—the carbonic oxide and the carbonic acid.

Carbonic Oxide is usually obtained by subjecting carbonic acid to the action of substances which abstract a portion of its oxygen. Upon this principle, carbonic oxide gas is produced by heating chalk and charcoal, or chalk and iron or zinc filings. The gas should be well washed, and may be preserved over water. Its specific gravity to hydrogen is as 13,2 to 1; 100 cubical inches weighing 29,7 grains. It is fatal to animals, extinguishes flame, and burns with a pale blue lambent light when mixed with, or exposed to, atmospheric air. When a stream of carbonic oxide is burnt under a dry bell glass of air or oxygen, no moisture whatever is deposited. When two volumes of carbonic oxide and one of oxygen are acted on by the electric spark, a detonation ensues, and two volumes of carbonic acid are produced. Whence it appears, that carbonic acid contains just twice as much oxygen as carbonic oxide. Carbonic oxide may be considered as a compound of one volume of oxygen and one volume of gaseous carbon, or of one proportion of carbon and one of oxygen, the latter being so expanded as to occupy two volumes.

Chemistry.

The representative number of charcoal, as obtained by considering this gas as a compound of one proportion of charcoal and one of oxygen, is 5,7 and 5,7 carbon + 7,5 oxygen = 13,2 carbonic oxide.

Carbonic acid may be obtained by burning carbon, either pure charcoal or the diamond, in oxygen gas; the oxygen suffers no change of bulk, so that the composition of carbonic acid is easily learned by comparing its weight with that of an equal volume of pure oxygen; 100 cubic inches of oxygen weigh 33,75 grains; 100 cubic inches of carbonic acid weigh 46,57 grains; hence 100 cubical inches of carbonic acid must consist of 33,75 grains of oxygen, + 12,82 grains of carbon, and 12,82 : 33,75 :: 5,7 : 15. Hence one proportion of charcoal = 5,7 + 2 proportions of oxygen, = 15, will constitute carbonic acid, represented by the number 20,7.

Carbonic acid is a most abundant natural product; the best mode of procuring it for experiment consists in acting upon pounded marble (carbonate of lime) by dilute muriatic acid. It may be collected over water, but must be preserved in vessels with glass stoppers, since water, at common temperature and pressure, takes up its own volume: under a pressure of two atmospheres it dissolves twice its volume, and so on. It becomes brisk and tart; by freezing, boiling, or exposure to the vacuum of the air-pump, the gas is given off again.

Carbonic Acid and Ammonia.—Carbonate of Ammonia.—These gases readily combine, and produce one of the most useful and best known of the ammoniacal compounds.

When one volume of carbonic acid and two volumes of ammonia are mixed in a glass vessel, over mercury, a complete condensation ensues, and a subcarbonate of ammonia is produced.

It consists of 16 ammonia + 20,7 carbonic acid, and is represented by 36,7.

Carbonic Acid. 20,7	Ammonia. 16.	= 36,7.
------------------------	-----------------	---------

If water be present, it so far overcomes the elasticity of the gas, as to enable the salt formed to take up another volume of carbonic acid, and thus a bicarbonate is formed.

Subcarbonate of ammonia crystallizes in octoëdrons, though it is generally met with in cakes broken out of the subliming vessel, being obtained by sublimation from a mixture of muriate of ammonia and chalk. Its odour is pungent; its taste hot and saline. A pint of water at 60° dissolves rather less than 4 ounces; by exposure to air it loses ammonia, and becomes a bicarbonate.

Chlorine and carbon do not combine; but *chlorine* unites with *carbonic oxide*, and produces a triple compound, called by Dr Davy *phosgene gas*, as it is most easily produced by exposing a mixture of equal volumes of chlorine and carbonic oxide to the action of light. A condensation = 0,5 takes place. The compound has a peculiar pungent odour. It is soluble in water, and is resolved into carbonic and

Chemistry.

muriatic acid gases. The weight of phosgene to hydrogen is as 46,7 to 1. 100 cubical inches weigh 107,075 grains. It condenses four times its volume of ammoniacal gas, producing a peculiar compound of a white colour.

Carbon and Hydrogen.—These bodies combine in two proportions, and form gaseous compounds, consisting of 1 carbon + 1 hydrogen, and 1 carbon + 2 hydrogen.

There are several processes by which they may be obtained. The first compound is obtained by the decomposition of alcohol by sulphuric acid. It may be collected over water; its specific gravity to hydrogen is 13,4. 100 cubic inches weigh 30,15 grains.

This gas is inflammable, burning with a bright yellowish white flame. One part by volume requires for perfect combustion three of oxygen, and two of carbonic acid result. When sulphur is heated in one volume of this gas, charcoal separates, and two volumes of sulphuretted hydrogen result. As hydrogen suffers no change of volume by combining with sulphur, it follows that carburetted hydrogen contains two volumes of hydrogen condensed into one, hence the quantity of oxygen required for its consumption.

Before detonation.

After detonation.

C. Hyd. 5,7 + 1	Oxygen. 7,5
	7,5
	7,5

Hydrogen. 1	Oxygen. 7,5	Water.
----------------	----------------	--------

Carbon.

5,7	Oxygen. 7,5	} Carbonic acid.
	7,5	

This gas, therefore, is constituted of 1 proportion of charcoal = 5,7 + 1 proportion of hydrogen = 1, and its number is 6,7.

When this gas is mixed with chlorine in the proportion of 1 to 2 by volume, the mixture on inflammation produces muriatic acid, and charcoal is abundantly deposited; but if the two gases be mixed in an exhausted vessel, or over water, they act slowly upon each other, and a peculiar fluid is formed, which appears like a heavy oil, hence this variety of carburetted hydrogen has been termed *olefant gas*.

The other variety of carburetted hydrogen is often generated in stagnant ponds. It may be procured by passing the vapour of water over red-hot charcoal, and washing the gas thus afforded in lime-water, by which the carbonic acid is separated. 100 cubic inches of this gas weigh only 17,325 grains, so that its specific gravity to hydrogen is 7,7. It burns with a pale blue flame. It requires for perfect combustion twice its volume of oxygen; water is generated, and one volume of carbonic acid results, so that it contains only half the quantity of carbon existing in the former compound, or it may

Chemistry.

The third division of undecomposed bodies embraces the *Metals*. Their general properties, and those of their most important compounds, are, with few exceptions, amply detailed in the body of the work. On the present occasion, it will be required to notice those of more recent discovery, and point out the applications of the law of proportions to their various combinations.

Chemists have adopted different principles of subdivision in regard to the metals, sometimes founding them upon their mechanical, and sometimes upon their chemical qualities. In the former case, malleability, ductility, or tenacity, have been selected as leading characters; in the latter, fusibility and the action of heat and air have furnished characters for classification.

In the present state of our knowledge, it seems that the relative attractions of the metals for oxygen may be most usefully and scientifically assumed as the basis of arrangement, and they may be thus classified under five heads.

The first embraces those metals which neither absorb oxygen nor decompose water at any temperature; their oxides are reducible at a heat below redness.

1. Gold.
2. Silver.
3. Platinum.
4. Palladium.
5. Rhodium.
6. Iridium.

The second division contains metals which, when heated to a *certain* temperature, absorb and retain oxygen; at higher temperatures they again give it off.

1. Osmium.
2. Mercury.
3. Lead.
4. Nickel.

The metals of the third division absorb oxygen even when at a temperature above redness. They are incapable of decomposing water at any temperature.

- | | |
|----------------|-----------------------|
| 1. Arsenic. | } Acidifiable metals. |
| 2. Molybdenum. | |
| 3. Chrome. | |
| 4. Tungsten. | |
| 5. Columbium. | |
| 6. Antimony. | |
| 7. Uranium. | |
| 8. Cerium. | |
| 9. Cobalt. | |
| 10. Titanium. | |
| 11. Bismuth. | |
| 12. Copper. | |
| 13. Tellurium. | |

The metals of the fourth division absorb oxygen even at high temperatures, and, when heated to redness, are capable of decomposing water.

1. Iron.
2. Tin.

3. Zinc.

4. Manganese.

Chemistry.

The fifth class includes metals which absorb oxygen, and which rapidly decompose water, at all temperatures.

1. Potassium.
2. Sodium.
3. Barium.
4. Strontium.
5. Calcium.
6. Magnesium.

The sixth class includes bodies which, by analogy, are considered metallic, but of which the oxides have not hitherto been reduced.

1. Silicium.
2. Aluminium.
3. Zirconium.
4. Ittrium.
5. Glucium.

It appears from this statement that the metals are thirty-eight in number.

If we arrange the metals according to their specific gravities, they stand as follows:

1. Platinum,	21.00
2. Gold,	19.30
3. Tungsten,	17.50
4. Mercury,	13.50
5. Palladium,	11.50
6. Lead,	11.35
7. Silver,	10.50
8. Bismuth,	9.80
9. Uranium,	9.00
10. Copper,	8.90
11. Arsenic,	8.35
12. Nickel,	8.25
13. Cobalt,	8.00
14. Iron,	7.78
15. Molybdenum,	7.40
16. Tin,	7.30
17. Zinc,	7.00
18. Manganese,	6.85
19. Antimony,	6.70
20. Tellurium,	6.10
21. Sodium,	0.972
22. Potassium,	0.865

It will be seen, therefore, that the metals include the heaviest and lightest solids. Of the remaining metals, the specific gravities have not been ascertained.

1. Gold.

Gold occurs in nature in a metallic state, alloyed with a little silver or copper: it may be obtained pure by dissolving it in nitro-muriatic acid, evaporating the solution to dryness, redissolving the dry mass in distilled water, filtering, and adding to it a solution of sulphate of iron; a black powder falls, which, after having been washed with dilute muriatic acid and distilled water, affords on fusion a button of pure gold.

Chemistry. Pure gold is of a deep yellow colour. It melts at a bright red heat, and, when in fusion, appears of a brilliant green colour. It shows no tendency to unite to oxygen when exposed to its action in a state of fusion; but if an electric discharge be passed through a very fine wire of gold, a purple powder is produced, which has been considered as an oxide.

Oxide of Gold may be obtained by adding a solution of potash to a solution of chloride of gold; the precipitate must be washed first with weak solution of potash, and then with water, and dried at a temperature of 100°. If this be regarded as a protoxide, that is, as consisting of 1 proportion of gold + 1 of oxygen, then the number 97 will represent gold, and this oxide will consist of 97 gold + 7,5 oxygen = 104,5.

Chloride of Gold.—When gold in a state of minute division is heated in chlorine, a compound of a deep yellow colour results, which consists of 97 gold + 33,5 chlorine. When acted upon by water, a *muriate* of gold is produced.

The action of iodine in gold has scarcely been examined.

Nitrate of Gold.—The nitric acid has scarcely any action upon gold, but it readily dissolves the oxide, forming a yellow styptic deliquescent salt.

Fulminating Gold.—This compound is obtained by adding ammonia to a solution of muriate of gold. It is a yellow powder, which, when gently heated, explodes with some violence. The results of its decomposition are metallic gold, water, and nitrogen.

Sulphuret of Gold is procured by passing sulphuretted hydrogen through an aqueous solution of muriate of gold. It is a black substance consisting of 97 gold + 30 sulphur.

Phosphuret of Gold is obtained by heating gold leaf with phosphorus, in a tube deprived of air. It is a grey substance of a metallic lustre, and consists of 97 gold + 20 phosphorus.

Silver.

Silver occurs in nature pure, and alloyed with gold, antimony, arsenic, and bismuth—also combined with sulphur, and with chlorine, and in some triple combinations, such as the sulphuret of arsenic and silver, and of antimony and silver.

To obtain pure silver, the metal as it occurs in commerce may be dissolved in nitric acid; solution of common salt is added to that of silver, as long as it causes a precipitate—which is to be washed, dried, and ignited with twice its weight of subcarbonate of potash—a button of pure silver is thus procured.

Silver is a white metal, and when in fusion, very brilliant. It melts at a cherry red heat, and is not oxidized by exposure to air.

Oxide of Silver may be procured by adding a solution of barytes to one of nitrate of silver; a grey powder is precipitated, which, when washed and dried, consists of 102 silver + 7,5 oxygen.

Chloride of Silver is obtained by adding solution of chlorine, or of muriatic acid, to nitrate of silver. It is white, and fusible by a gentle heat into a semi-transparent mass (Luna Cornea). It consists of 102 silver + 33,5 chlorine.

Fulminating Silver is a compound of ammonia and

oxide of silver, more violent in its operation than fulminating gold.

Nitrate of Silver.—The nitric acid diluted with 3 or 4 parts of water readily oxidizes and dissolves silver, and by evaporation a crystallized nitrate of silver is obtained, consisting of 109,5 oxide of silver + 50,5 nitric acid.

Sulphuret of Silver is obtained by the action of sulphuretted hydrogen upon an aqueous solution of nitrate of silver; it is of a dark grey colour, and often found in silver mines. It consists of 102 silver + 15 sulphur.

Sulphate of Silver is a white salt which crystallizes in fine needles, very difficultly soluble in water. It is procured by adding nitrate of silver to sulphate of soda, and then falls as a white precipitate. It easily dissolves in sulphuric and nitric acids, and in ammonia. It consists of 109,5 oxide + 37,5 sulphuric acid.

Phosphate of Silver, a pale yellow compound obtained by pouring phosphoric acid into nitrate of silver. It is insoluble in water, but dissolves in phosphoric acid.

Carbonate of Silver is formed by adding solution of carbonate of potash to nitrate of silver. It is of a pale yellow colour, but, like most other salts of silver, blackens when exposed to light. It consists of 109,5 oxide + 20,7 acid.

Cyanuret of Silver.—A white compound obtained by adding prussiate (hydrocyanate) of potash to nitrate of silver.

Borate of Silver.—An insoluble white powder.

Platinum

Is found in small grains in South America, confined to alluvial strata: The pure metal may be obtained by dissolving crude platinum in nitro-muriatic acid, and precipitating by a solution of muriate of ammonia. This first precipitate is dissolved in nitro-muriatic acid, and again precipitated as before. The second precipitate is heated white hot, and pure platinum remains. It is a white metal, extremely difficult of fusion, and unaltered by the joint action of heat and air.

Oxide of Platinum is procured by adding excess of potash to muriate of platinum. It falls as a black powder, composed of 92 metal + 7,5 oxygen.

Chloride of Platinum may be formed by heating the muriate in close vessels. It has not been particularly examined.

Muriate of Platinum is obtained by evaporating the nitro-muriatic solution; it is acrid, deliquescent, and difficultly crystallizable. It forms a triple compound with ammonia, of difficult solubility.

Sulphuret of Platinum is formed by heating the finely divided metal with sulphur in close vessels. It is a black, brittle compound, and consists of 92 platinum + 15 sulphur.

The four following metals have been discovered in the ore of platinum by Dr Wollaston and Mr Tennant.

Palladium and Rhodium.

These metals are obtained as follows: Dissolve

Chemistry. crude platinum in nitro-muriatic acid, precipitate by sal-ammoniac, and filter. The filtered liquor may contain iron, copper, lead, gold, platinum, palladium, and rhodium. Immerse a plate of iron, which will precipitate all the above metals except iron; digest this precipitate in dilute nitric acid, which will dissolve the lead and copper; then in nitro-muriatic acid, which takes up platinum, palladium, and rhodium; add to this solution some common salt, which forms triple compounds with the three metals. Alcohol dissolves two of these, and leaves the triple salt of rhodium; this is to be dissolved in water, and a plate of zinc immersed into the solution, which precipitates metallic rhodium.

Rhodium is characterized by the rose colour of many of its salts. It is not precipitated either by muriate or hydrosulphuret of ammonia.

The triple salts of palladium and of platinum may be decomposed by prussiate of potash, which throws down the former, and from which the metal may be obtained by ignition.

Palladium is a white metal, malleable and ductile.

Iridium.

When the ore of platinum is digested in nitro-muriatic acid, there remains a black powder, which, when alternately acted upon by muriatic acid and soda, is for the most part dissolved. The acid solution contains iridium, and by evaporation and exposure to heat, the metal is obtained. Its colour is that of platinum; it appears almost infusible. Its combinations have not been examined with precision.

Osmium.

Osmium is contained in the alkaline solution just alluded to. It may be obtained by distilling it with a little sulphuric acid. Its oxide passes over dissolved in water, from which solution it may be separated by mercury.

Osmium has a peculiar smell like new bread. Acids do not act upon it. Alkalies readily dissolve it. Tincture of galls added to its solution produces a vivid blue colour.

Mercury.

The principal ore of this metal is the sulphuret, or native cinnabar, from which the mercury is separated by distillation with quicklime, or iron filings.

Mercury is a brilliant white metal, with a tint of blue. It is liquid at all common temperatures, solid at 40° , and gaseous at 670° .

Mercury and Oxygen.—There are two oxides of mercury. 1. The black, or protoxyde, may be obtained by long agitation of the metal in contact with oxygen, or by washing the chloride of mercury (calomel) with hot lime-water. It is insipid, and consists of 190 M + 7.5 oxygen. 2. The red, or peroxide of mercury, is produced by exposing the metal heated nearly to its boiling point to the action of air. It becomes coated with red scales, spangles, and crystals, which consist of 190 mercury + 15 oxygen.

Chlorides of Mercury.—This metal also forms two compounds with chlorine; the chloride or *calomel*, composed of one proportion of mercury = 190 +

Chemistry. one of chlorine = 33.5, and the bichloride or *corrosive sublimate*, consisting of one proportion of mercury and two of chlorine, or $190 + 67$. These compounds, and especially the former, are most important pharmaceutical preparations. In the London *Pharmacopæia*, they are very improperly termed submuriate and oxymuriate of mercury.

Chloride of Mercury, or calomel, is produced by exposing to heat, in proper subliming vessels, a mixture of common salt and sulphate of mercury. Upon the large scale, the following are the best proportions: 50 lbs. of mercury are boiled with 70 lbs. of sulphuric acid to dryness in a cast-iron vessel. 62 lbs. of the dry salt are triturated with $40\frac{1}{2}$ lbs. of mercury, until the globules disappear, and 34 lbs. of common salt are then added. This mixture is submitted to heat in earthen vessels, and from 95 to 100 lbs. of calomel are the result. It is to be washed in large quantities of distilled water, after having been ground to a fine powder.

Calomel is a white crystallizable compound, insoluble in water, and unaltered by exposure to air; long exposed to light, it becomes brown.

Bichloride of Mercury, or corrosive sublimate.—When mercury is heated in chlorine, the metal burns with a white flame, and, combining with the gas, produces a white sublimate of bichloride; but the following process is usually adopted for the preparation of this compound: 5 parts of sulphuric acid are boiled with 4 of mercury to dryness; the dry mass is reduced to powder, and mixed with 4 parts of common salt, and 1 of black oxide of manganese. This mixture is put into a glass subliming vessel, and gradually heated to redness. The bichloride rises in the form of a white semitransparent crystalline mass. Corrosive sublimate has a disgustingly nauseous and astringent flavour, and is highly poisonous. At the temperature of 60° , it is soluble in 20 parts of water, and at 212° in about 3 parts. Alcohol dissolves nearly its own weight. With muriate of ammonia it produces a very soluble compound.

Mercury and Iodine produce a compound of a brilliant scarlet colour, or yellow with excess of mercury.

Mercury and Nitric Acid.—The results of the action of nitric acid upon mercury vary with the circumstances under which it has taken place. If excess of mercury be exposed to the action of dilute nitric acid, the metal is protoxidized, and the solution affords white prismatic crystals of an acrid and metallic taste. These are the *nitrate of mercury*. When put into water they are resolved into *supernitrate*, which dissolves, and into *subnitrate*, which is an insoluble yellow powder. The solution of nitrate of mercury furnishes a black precipitate of oxide with solution of potash, and a white precipitate of chloride with solution of common salt.

When nitric acid diluted with 4 parts of water is boiled on mercury, the acid being in excess, the metal is converted into peroxide, and a compound of nitric acid and peroxide of mercury, or an *oxynitrate of mercury* is formed. By evaporation irregular crystals, of a very acid taste, are obtained, which, by water, are resolved into a soluble *superoxynitrate*, and into an insoluble yellow *suboxynitrate*.

Chemistry. *Mercury and Sulphur.*—When these bodies are triturated together, a black powder results called formerly Ethiops mineral. When ten parts of mercury are heated in a matrass with one of sulphur, there is considerable action attended by ignition, and a violet coloured compound results, which affords, by sublimation, a crystalline mass, becoming, when reduced to powder, of a fine red hue. This is *Sulphuret of Mercury, Cinnabhr, or Vermillion*. It is tasteless, insoluble in water, and consists of 190 M. + 30 S.

Mercury and Sulphuric Acid.—*Sulphate of Mercury* is an insoluble white salt, obtained by adding sulphuric acid to a solution of nitrate of mercury. *Oxysulphate of Mercury* is formed by boiling the metal with the acid; it is peroxidized and dissolved; sulphurous acid is evolved, and a white crystallized mass remains. When this salt is put into water it is resolved into a *Superoxysulphate*, and into an insoluble *Suboxysulphate* of a yellow colour, and formerly called Turpeth mineral.

Phosphuret of Mercury is formed by heating phosphorus strongly with calomel; it is of a brown colour. *Phosphate of Mercury* is obtained by adding phosphate of soda to nitrate of mercury; it is white and insoluble in excess of acid. The *Oxyphosphate of Mercury* is soluble in excess of acid.

Carbonate of Mercury.—Carbonate of potash furnishes a yellow precipitate in solution of nitrate of mercury.

Mercury and Cyanogen.—The compound hitherto called Prussiate of Mercury consists, according to M. Gay-Lussac, of 80 mercury + 20 cyanogen. This compound, when distilled with muriatic acid, affords the hydrocyanic (prussic) acid. (See M. Gay-Lussac's *Memoir Annales de Chimie*, T. 98, p. 114, ann. 1815.)

Lead.

The natural compounds of this metal are very numerous. The most important is the sulphuret, whence the pure metal is chiefly procured. It is also found combined with carbonic, sulphuric, phosphoric, arsenic, molybdic, and chromic acids, and with oxygen and chlorine. To obtain lead perfectly pure, it may be dissolved in nitric acid,—the solution evaporated to dryness,—the dry mass redissolved in water and crystallized;—the crystals heated strongly with charcoal afford the metal quite pure.

Lead is of a bluish white tint,—it melts at 600°, and by the united action of heat and air is readily converted into an oxide.

Oxides of Lead.—There are three oxides of lead. The *protoxide* (massicot) is the basis of the salts; it may be obtained by heating the nitrate of lead to redness in a close vessel. It is insipid and insoluble in water,—of a pale yellow colour, and when fused crystallizes on cooling in irregular scales (litharge). It is very soluble in potash and soda, and when in fusion it readily dissolves several of the earthy bodies. If it be considered as a protoxide consisting of one proportion of lead and one of oxygen, then the number 97 will represent lead, and it will consist of 97 L. + 7,5 oxygen.

If the protoxide be exposed to heat and oxygen,

Chemistry. it gradually acquires a bright red colour, and is known under the name of Minium, or *deutoxide* of lead. This oxide, when exposed to nitric acid, is resolved into protoxide, which is dissolved, and into *peroxide*, which is an insoluble brown substance, consisting of 97 L. + 15 oxygen. Minium affords on analysis 97 L. + 11,25 oxygen, and may, therefore, be regarded as a definite compound of the protoxide and peroxide.

Lead and Chlorine.—Chloride of lead. When laminated lead is heated in chlorine, the gas is absorbed, and a chloride of lead results, composed of 97 L. + 33,5 C. The same substance is obtained by adding muriatic acid to nitrate of lead; it is white and fusible, and on cooling forms a horn-like substance (*plumbum corneum*). It dissolves in 22 parts of water at 60°.

Nitrate of Lead—obtained by dissolving the metal in dilute nitric acid, and evaporation. The salt crystallizes in tetraëdra and octoëdra. It is soluble in 8 parts of water at 212°. It consists of 104,5 oxide of lead + 50,5 nitric acid.

Lead and Sulphur readily combine and form a *sulphuret of lead*, composed of 97 L. + 15 S.

Sulphate of Lead is a white insoluble compound, containing 104,5 oxide of lead + 37,5 sulphuric acid. It is formed by adding dilute sulphuric acid to nitrate of lead.

Phosphate of Lead is a yellow insoluble compound obtained by adding phosphoric acid to nitrate of lead. It consists of 104,5 oxide + 25 acid.

Carbonate of Lead is an important compound, on account of its use in the arts; it is commonly called White Lead. It is formed by adding carbonate of potash to nitrate of lead, when a white precipitate falls, consisting of 104,5 oxide + 20,7 carbonic acid.

Nickel.

Nickel is found native, combined with arsenic, and with arsenic acid. It is procured pure by the following process: Dissolve the metal sold under the name of nickel in dilute nitric acid to saturation, and evaporate to dryness; redissolve in water, and add nitrate of lead sufficient to precipitate the arsenic acid; filter, and immerse a plate of iron to separate copper; filter again, and add solution of carbonate of potash; wash the precipitate thus occasioned, and put it, while moist, into liquid ammonia, which dissolves the oxides of nickel and cobalt, leaving impurities to be separated by a filter; add potash to the ammoniacal solution, which precipitates the oxide of nickel, and which, by ignition with charcoal, affords a globule of the pure metal. Nickel is a white metal, which acts upon the magnetic needle, and is itself capable of becoming a magnet. It is very difficultly fusible, but absorbs oxygen readily when heated red-hot.

Oxide of Nickel is obtained by adding potash to the solution of the nitrate—a precipitate falls of a pale green colour, which is a *hydrate* or compound of oxide of nickel with water,—this heated to redness, affords a grey oxide, consisting of 55,5 nickel + 15 oxygen.

When nickel is heated in chlorine, a *chloride* re-

Chemistry. **salts.** This compound may also be obtained by heating muriate of nickel to redness in a glass tube,—a yellow scaly body is obtained, consisting of 55,5 nickel + 67 chlorine.

Nitrate of Nickel is a deliquescent difficultly crystallizable salt. The *sulphate* may be formed by dissolving the oxide in dilute sulphuric acid; it crystallizes in four-sided prisms of a beautiful grass-green. (For an elaborate account of the combinations of nickel, see *Annales de Chimie*, 1816.)

Arsenic.

Arsenic exists in nature nearly pure, and frequently occurs combined with other metallic substances.

The pure metal is obtained by heating a mixture of charcoal and *white arsenic* in a tube or retort,—it sublimes in small brilliant scales. Arsenic is a very inflammable, fusible, and volatile metal, and when heated in contact with the air, produces white fumes of a peculiar alliaceous odour.—It is highly poisonous in all its combinations.

Arsenic and Oxygen combine in two proportions, and produce compounds which have acid properties,—they have consequently been termed the arsenious and arsenic acids.

Arsenious Acid or *White Arsenic* is chiefly obtained by sublimation from certain ores, especially those of cobalt. It is met with in commerce as a semitransparent brittle body, of an acrid nauseous taste, soluble in 80 parts of water at 60°. The solution reddens vegetable blues,—it is equally soluble in alcohol. It is composed of 45 arsenic + 15 oxygen. It combines with metallic oxides, and produces a class of salts which have been termed arsenites. Some of these are produced by adding the solution of white arsenic to that of the other metallic oxide; others are best formed by adding solution of arsenite of potash to the other metallic salts.

Arsenic Acid is obtained by distilling four parts of nitric acid and one of arsenious acid to dryness. The white mass which remains is more sour and soluble than the white arsenic, and it constitutes a different set of salts, which are called arseniates. It consists of 45 arsenic + 22,5 oxygen.

The arsenious acid forms uncrystallizable compounds with the alkalies. The *arsenite of ammonia* is easily formed by digesting finely powdered white arsenic in solution of ammonia. The arsenites of potash and soda may be formed in the same way.

The soluble *arsenates*, on the other hand, are crystallizable. The *arsenate of ammonia* forms rhomboidal crystals. Neither the salts of gold nor those of platinum furnish any precipitates with the acids of arsenic, nor with the arseniate or arsenite of potash. Silver is precipitated white by arsenite of potash; but the solution of arsenious acid renders solution of nitrate of silver slightly turbid only. Arsenic acid, on the contrary, produces a copious reddish brown precipitate in solution of nitrate of silver, which is *arseniate of silver*. The arsenious acid forms dirty white precipitates in the solutions of nitrate and oxynitrate of mercury. The arsenic acid produces no precipitate in either, but the arseniate of potash a yellowish precipitate in both.

Nitrate of lead furnishes no precipitate with arse-

nious acid: but the arsenite of potash forms a white *arsenite of lead*. The arsenic acid, and the arseniate of potash, added to solution of nitrate of lead, instantly form insoluble white precipitates of *arseniate of lead*.

The *arseniate of nickel* is a very pale green precipitate obtained by adding arseniate of potash to nitrate of nickel. The *arsenite* of nickel has the same appearance.

Arsenic and Chlorine act upon each other with great energy,—the metal burns, the gas is absorbed, and a *chloride of arsenic* results, having at first the appearance of white fumes, which condense into a thick fluid, volatile and caustic, and which at a low temperature congeals. (Butter of arsenic.) It consists of 45 arsenic + 67 chlorine. When mixed with water it affords *muriate of arsenic*.

Arsenic and Iodine, when heated together, produce a red sublimate, which, acted upon by water, furnishes hydriodic and arsenic acids.

Arsenic and Hydrogen.—When an alloy of arsenic and potassium is thrown into water, a brown *hyduret of arsenic* results. When arsenic is presented to nascent hydrogen, as when a mixture of white arsenic and zinc filings is exposed to the action of dilute sulphuric acid, the metal is dissolved by the gas, and we thus obtain the *arsenuretted hydrogen gas*. It may be collected and preserved over water. The composition, and consequently the specific gravity of this gas, vary,—and no accurate results have hitherto been obtained concerning it. When inflamed in contact with air, it produces white oxide of arsenic and water, and hyduret of arsenic is deposited upon the vessels. When chlorine is allowed to bubble up into this gas standing over water, inflammation frequently occurs,—hyduret of arsenic is deposited, and chloride of arsenic formed. When decomposed, one volume of arsenuretted hydrogen appears to afford 1,5 volumes of hydrogen.

There are two *sulphurets of arsenic*, the one of a bright red colour, called Realgar,—the other yellow, and known in commerce under the name of Orpiment.

The sulphuric acid dissolves the arsenious acid, and forms a difficultly soluble *sulphate of arsenic*.

Alloys.—With gold, platinum, and silver, arsenic forms brittle compounds of comparatively easy fusion,—it amalgamates with mercury, produces a brittle alloy with lead, and with nickel forms a reddish compound. The latter metal is indeed generally found alloyed with arsenic.

Molybdenum.

The sulphuret is the most common natural compound of this metal. To procure the metal the native sulphuret is powdered and exposed under a red-hot muffle, till converted into a grey powder, which is to be digested in ammonia, and the solution filtered and evaporated to dryness. The residuum is dissolved in nitric acid, reevaporated to dryness, and violently heated with charcoal. The metal is, of a whitish grey colour, and of excessively difficult fusion.

Molybdenum and Oxygen, when exposed to heat, and oxygen molybdenum is acidified, a white crystalline sublimate of *Molybdic Acid* being formed.

Chemistry. There are two other compounds with oxygen—the one black, obtained by heating molybdic acid with charcoal; the other blue, and procured by immersing tin in solution of molybdic acid.—The black oxide consists of

the blue (molybdous acid) 44 M. + 7,5. oxy.
the white (molybdic acid) 44 M. + 15.—
These acids combine with certain bases forming molybdates and molybdates. Molybdate of silver, of mercury, of lead, and of nickel, may be procured by adding molybdic acid to the respective nitrates of those metals.

Sulphuret of Molybdenum is a sectile compound of a metallic lustre, composed of 44 M. + 30 S.

Chrome.

The native combinations of chrome are the oxide, and the chromates of lead and iron.

By violently igniting the oxide with charcoal a white, brittle, and very difficultly fusible metal is obtained.

Chrome and Oxygen.—The *Oxide of Chrome* is of a green colour, and may be procured by exposing chromic acid to a red heat.

Chromic Acid may be obtained by digesting native chromate of lead in fine powder, in carbonate of potash. A chromate of potash is produced, to which sulphuric acid is added; by evaporation sulphate of potash and crystals of chromic acid are obtained. Chromic acid is of a red colour, and very soluble in water.

The other combinations of chrome are very imperfectly known.

Tungsten.

There is a mineral called Tungsten, which is a native tungstate of lime, and another called Wolfram, consisting of tungstic acid, iron, and manganese. To obtain the metal, either of its oxides are violently ignited with charcoal—in colour it resembles iron—it is hard and brittle.

Oxides of Tungsten.—This metal unites in two proportions with oxygen. The black oxide may be obtained by igniting the peroxide with charcoal. Its properties have not been investigated.

The peroxide, or *Tungstic Acid*, is obtained from native tungstate of lime, which is fused with four times its weight of subcarbonate of potash. The fused mass is dissolved in water, and nitric acid added to the filtered solution which precipitates the tungstic acid. This body is of a yellow colour—it unites with the alkalies, and forms soluble salts.

Columbium.

This metal was first discovered by Mr Hatchett in a mineral from North America. It is found combined with the oxides of iron and manganese, and also with yttria, in the minerals called tantalite and ytthro-tantalite. The peroxide of columbium is almost insoluble in nitric and sulphuric acids, but when freshly precipitated it dissolves in oxalic, tartaric, and nitric acids, and very readily in potash.

Antimony.

This metal is found native, but its principal ore is

the *Sulphuret*, from which pure antimony may be obtained by the following process: Mix three parts of the powdered sulphuret with two of crude tartar, and throw the mixture by spoonfuls into a red-hot crucible; then heat the mass to redness, and a button of metal will be found at the bottom of the crucible. Reduce this button to fine powder, and dissolve it in nitro-muriatic acid—pour this solution into water, which will occasion the precipitation of a white powder, which is to be mixed with twice its weight of tartar, and exposed to a dull red heat in a crucible. The button now obtained is pure antimony.

Antimony is of a silvery white colour, brittle and crystalline in its ordinary texture. It fuses at 800° Fahrenheit.

Antimony and Oxygen.—These bodies form two well defined compounds, the history of which is of great importance to the pharmaceutical chemist.

The *Protoxide of Antimony* is thus obtained: To 200 parts of sulphuric acid add 50 parts of powdered metallic antimony. Boil the mixture to dryness, wash the dry mass first in water, and then with a weak solution of subcarbonate of potash, a white powder remains, which, when thoroughly washed with hot water, is *Protoxide of Antimony*.

This protoxide exists in all the active antimonial preparations—in emetic tartar, kermes, glass of antimony, golden sulphuret, &c. It consists of 85 A. + 15 oxygen. It is fusible and volatile at a red heat, decomposed by sulphur and charcoal; and, when acted on by nitric acid, is converted into peroxide.

Peroxide of Antimony is procured by acting upon the powdered metal by excess of hot nitric acid. It is of a yellow white, difficultly fusible, and does not form soluble salts with acids. It consists of 85 ant. + 22,5 oxygen. The diaphoretic antimony of old Pharmacopœia consisted of this oxide.

Antimony and Chlorine combine in one proportion only to produce the chloride of antimony. (Butter of Antimony.) The powdered metal takes fire when thrown into the gas, and a compound, at first liquid, but afterwards concreting, is formed. It may also be produced by the distillation of antimony and bichloride of mercury, or by heating the solution of protoxide of antimony in muriatic acid. It consists of 85 A. + 67 C. When water is added to the chloride of antimony, a mutual decomposition ensues, and protoxide of antimony and muriatic acid result.

Sulphuret of Antimony is easily formed by fusing the metal with sulphur. It consists of 85 A. + 30 S.

Sulphate of Antimony.—When sulphuric acid is boiled upon finely powdered antimony, the metal is oxidized, and an acid sulphate and a subsulphate of antimony are the results. In both these salts the metal is in the state of protoxide.

Hydrosulphuretted Oxide of Antimony.—This compound has long been known under the name of *Kermes Mineral*. It is commonly prepared as follows: Equal parts of sulphuret of antimony and common potash are fused together; the resulting mass is finely powdered, and boiled in ten times its weight

Chemistry. of water. The liquor is filtered while hot; and, during cooling, it deposits *kermes*. The mother liquor of *kermes* deposits a copious yellowish red precipitate upon the addition of dilute sulphuric acid, which, when washed and dried, is known under the name of golden sulphur of antimony. It is improperly called in the London Pharmacopœia *antimonii sulphuretum præcipitatum*.

In forming these compounds, the following changes seem to have taken place. The sulphuret of antimony and potash acts upon the water, a portion of which is decomposed; hydrogen is transferred to the alkaline sulphuret to form hydrosulphuret of potash; hydrogen and oxygen unite to the sulphuret of antimony, producing a hydrosulphuretted oxide of that metal (*kermes*), which remains dissolved in the hot alkaline hydrosulphuret, and of which one portion is precipitated as that solution cools. When dilute sulphuric acid is added, the hydrosulphuret of potash is decomposed, sulphate of potash is formed, and sulphur and sulphuretted hydrogen are liberated; the sulphur falls in combination with the *kermes*, producing the *golden sulphur*, or sulphuretted hydrosulphuret.

Uranium.

The oxide and the sulphuret are the principal native combinations of uranium. To obtain the metal from the sulphuret, it is heated in a muffle, and digested in nitro-muriatic acid; the oxide of uranium is precipitable from this solution by potash; and, when exposed to an intense heat with charcoal, it affords the metal. It is grey, and extremely difficultly fusible.

Very few experiments have hitherto been made upon this metal. The oxide precipitated from its nitric solution by alkalies is yellow, but by heating with charcoal it becomes black. The uranitic ore, called by the Germans *Uran glimmer*, is a hydrate of the yellow oxide. The salts of uranium have a yellow colour and an astringent metallic taste. Potash forms in their solutions a yellow precipitate, and carbonate of potash a white precipitate; both these precipitates are redissoluble in excess of alkali.

Cerium.

This metal has been obtained by Hisinger and Berzelius from a mineral found at Bastnas in Sweden, to which they have given the name of *cerite*. The ore is calcined, pulverised, and digested in nitro-muriatic acid. To the filtered solution, saturated with potash, oxalic acid is added, which occasions a precipitate; this, when dried and ignited, is *oxide of cerium*.

There are two oxides of cerium, the red or *protoxide*, and the white or *peroxide*. The salts of cerium have a sweetish taste. Those formed with the protoxide are colourless, those with the peroxide are yellow.

Cobalt.

The native combinations of cobalt are the oxide, the compound of the metal with iron, nickel, arsenic, and sulphur. It is also found combined with arsenic acid.

To obtain the pure metal, the substance called

Chemistry. *zaffre*, which is an impure oxide of cobalt, may be detonated three or four times with half its weight of nitre, then washed in hot water, and the residue digested in nitric acid. The nitric solution, when filtered and evaporated, yields an oxide, which, by ignition with charcoal, affords cobalt. Cobalt is of a grey colour, brittle, and difficultly fusible.

Cobalt and Oxygen unite in two proportions. The *protoxide* is formed by adding potash to the nitrate, and drying the precipitate; it appears reddish black. By exposure to heat and air, it absorbs an additional portion of oxygen, and is thus converted into black *peroxide*. The protoxide, when recently precipitated and moist, is blue; and, if left in contact of water, becomes a red *hydrate*.

Cobalt, when heated in chlorine, burns; but the *chloride of cobalt* has not been examined.

The salts of cobalt all contain the protoxide, and are of a red colour; the alkalies produce in them bluish precipitates, which redissolve in excess of ammonia. Prussiate of potash forms a grass-green precipitate; and phosphoric, carbonic, arsenic, and oxalic acids, form insoluble precipitates of a red colour.

Muriate of Cobalt is a deliquescent salt, of a blue green colour; when a little diluted, it becomes pink; the pale pink solution, when written with, is scarcely visible; but, if gently heated, the writing appears in brilliant green, which soon vanishes as the paper cools, in consequence of the salt absorbing the aerial moisture.

With nitric acid, the oxide of cobalt furnishes a red deliquescent *nitrate of cobalt*.

Sulphuret of Cobalt is formed by heating the oxide with sulphur.

Sulphate of Cobalt forms red rhombic crystal.

Phosphuret of Cobalt is a white brittle compound.

Phosphate of Cobalt may be formed by double decomposition, as by adding phosphate of soda to muriate of cobalt; it is insoluble; of a purple colour; and, if mixed with eight parts of gelatinous alumina, and heated, it produces a beautiful blue, which may sometimes be employed by painters as a substitute for ultramarine.

Titanium.

Titanium exists in the state of oxide, in two minerals—in titanite and in menachanite. The metal may be obtained from the former by fusion with potash; the fused mass, washed with water, leaves oxide of titanium, containing a little iron; it is to be dissolved in muriatic acid, and precipitated by oxalic acid. The oxalate affords the metal by intense ignition with charcoal.

Titanium is of the colour of copper. It is oxidized by exposure to heat and air, and is said to be susceptible of three degrees of oxidizement, the colours of the oxides being blue, red, and white.

Bismuth

Is found native, combined with oxygen, and with arsenic and sulphur. The metal may be obtained pure by dissolving the bismuth of commerce in nitric acid; water is added to the nitric solution, which separates oxide of bismuth. This oxide is easily re-

Chemistry. duced in the usual way. Bismuth is a brittle brilliant white metal, with a slight tint of red; it fuses at 476° , and always crystallizes on cooling. When exposed to heat and air it oxidizes, forming the white oxide. It consists of 66,5 bismuth + 7,5 oxygen.

Chloride of Bismuth is procured by heating the metal in the gas. It is a fusible volatile substance, decomposed by water; consisting of 66,5 B + 33,5 C.

Nitrate of Bismuth crystallizes in small four-sided prisms, consisting of 74 oxide + 50,5 acid. It is decomposed by water, and the oxide of bismuth is thrown down in the form of fine white powder. (Magistery of Bismuth, Pearl white, &c.)

Sulphuret of Bismuth is of a bluish colour and metallic lustre; it consists of 66,5 B. + 15 sulphur.

Sulphate of Bismuth consists of 74 oxide + 37,5 acid; it is a white compound insoluble in, but decomposed by water, which converts it into a subsulphate and supersulphate.

Bismuth forms alloys, some of which are remarkable for their fusibility. With gold, platinum, and silver, it forms brittle compounds. A compound of 8 parts of bismuth, 5 of lead, and 3 of tin, liquifies at 212° ; it is called *fusible metal*. The addition of 1 part of quicksilver renders it yet more fusible.

Copper.

This metal is found native, and in various states of combination. Of its ores, the oxide, chloride, sulphuret, sulphate, phosphate, carbonate, and arseniate, are the most remarkable. The metal may be obtained perfectly pure by dissolving the copper of commerce in muriatic acid; the solution is diluted, and a plate of iron is immersed upon which the copper is precipitated; it may be fused into a button.

Copper has a fine red colour and much brilliancy; it is very malleable and ductile, and has a peculiar smell when warmed or rubbed. It melts at a cherry red or dull white heat.

Copper and Oxygen.—There are two oxides of copper. The red or protoxide occurs native. It may be formed artificially, by dissolving a mixture of metallic copper, and peroxide of copper, in muriatic acid. When potash is added to this solution, a hydrated protoxide of an orange colour falls; if quickly dried out of the contact of air, it becomes of a red brown; it consists of 60 copper + 7,5 oxygen. The peroxide of copper is procured by precipitating nitrate of copper by potash, washing the precipitate, and exposing it to a red heat. It is black, and consists of 60 copper + 15 oxygen.

Copper and Chlorine.—Gaseous chlorine acts upon copper with great energy, and produces two chlorides, the one a fixed fusible substance, which is the chloride, consisting of 1 proportion of copper = 60 + 1 proportion of chlorine = 33,5. The other a volatile yellow substance, which is a bichloride, and contains 60 copper + 67 chlorine. These compounds furnish, with water, a solution of muriate of copper.

Nitric Acid, diluted with three parts of water, rapidly peroxidizes copper, forming a bright blue solution, which affords deliquescent prismatic crystals on evaporation. It consists of 75 oxide + 50,5

acid. Potash forms, in this solution, a bulky blue precipitate of hydrated peroxide of copper.

If ammonia be added to solution of nitrate of copper, it occasions also a precipitate of hydrate, but if it be added in excess, the precipitate is redissolved, and a triple compound produced. Ammonia also dissolves the peroxide of copper; forming a crystallizable compound of an intense blue colour.

Copper and Sulphur.—There are two sulphurets of copper, both of which exist native; the one is black, and may be formed artificially, by heating a mixture of copper filings and sulphur; as soon as the latter melts a violent action ensues, the copper becomes red hot, hydrogen escapes, and a black brittle body is formed, consisting of 60 copper + 15 sulphur.

The Bisulphuret is a common ore of copper called *Pyrites*. It consists of 60 copper + 30 sulphur, and is of a golden yellow colour.

Copper and Sulphurous Acid.—Sulphite of Copper may be obtained by passing sulphurous acid into water, through which peroxide of copper is diffused. Small red crystals are formed, composed of protoxide of copper and sulphurous acid.

Copper and Sulphuric Acid.—Oxisulphate of Copper—*Blue Vitriol.*—This salt is formed by dissolving peroxide of copper in sulphuric acid; it crystallizes in rhomboidal prisms of a fine blue colour. It is produced upon a large scale, by exposing roasted sulphuret of copper to air and moisture. It consists of 75 peroxide + 75 sulphuric acid; when crystallized, it contains 5 proportions of water, and consequently its composition will stand thus:

1 proportion peroxide,	75.
2 proportions sulphuric acid,	75.
5 proportions of water,	42.5
	192.5

By cautiously adding ammonia to a solution of the foregoing salt, a subsulphate of copper is precipitated, consisting of 150 oxide + 37,5 acid. The alkalies precipitate hydrated peroxide from the solution of this salt, and excess of ammonia forms a triple sulphate.

Phosphorus and Copper form a grey brittle phosphuret.

Phosphate of Copper may be formed by mixing solution of sulphate of copper with phosphate of soda; it is a blue green insoluble powder, composed of 75 oxide + 25 acid.

Carbonate of Copper, artificially prepared by adding carbonate of potash to sulphate of copper, is a green insoluble compound, containing 75 oxide + 20,7 acid. *Verditer* is a mixture of this carbonate with chalk; it is obtained by adding chalk to solution of nitrate of copper.

Many of the alloys of copper are important. With gold it forms a fine yellow ductile compound, used for coin and ornamental work. Sterling or standard gold consists of 11 gold + 1 copper. The specific gravity of this alloy is 17,157. With silver, it forms a white compound, used for plate and coin. Lead and copper require a high red heat for union—the alloy is grey and brittle.

The ores of tellurium are, 1. *Native*, in which the metal is combined with iron and a little gold. 2. *Graphic ore*, which consists of tellurium, gold, and silver. 3. *Yellow ore*, a compound of tellurium, gold, lead, and silver; and 4. *Black ore*, consisting of the same metals with copper and sulphur.

The metal is extracted from these ores by precipitating their diluted nitro-muriatic solution by potash, which is added in excess; the clear liquor is poured off and saturated with muriatic acid, which affords a precipitate of oxide of tellurium. This heated in a glass retort with charcoal furnishes the metal. Tellurium is of a bright grey colour, brittle, easily fusible, and very volatile. It burns with a blue flame, and produces a yellowish *oxide*, composed of 37 tell. + 7,5 oxy.

Chloride of Tellurium is white, and consists of 37 T. + 33,5 C.

Tellurium combines with hydrogen, producing *Telluretted hydrogen gas*. The soluble salts of tellurium furnish white precipitates, when neutralized by alkalies, which are soluble in excess either of the solvent or precipitant.

Iron.

The most important native combinations of iron, whence the immense supplies for the arts of life are drawn, are the oxides. Iron is also found combined with sulphur, and with several acids; it is so abundant that there are few fossils free from it. It is also found in some animal and vegetable bodies. Iron is a metal of a blue white colour, very malleable and ductile, and fusible at a white heat.

Iron and Oxygen.—Exposed to heat and air, iron quickly oxidizes. It unites with oxygen in at least two proportions. The *protoxide* may be procured by precipitating a solution of sulphate of iron by potash, washing the precipitate out of the contact of air, and drying it at a red heat. It is black, and consists of 52 iron + 15 oxygen.

When this oxide is boiled in nitric acid, and precipitated by ammonia, washed, and dried at a low red heat, it increases in weight, and acquires a brown colour. This is the *peroxide* composed of 52 iron + 22,5 oxygen. These oxides form distinct salts with the acids. The salts containing the black oxide are of a green colour, mostly crystallizable, become reddish brown by exposure to air, are insoluble in alcohol, and their solutions absorb nitric oxide gas and become of a deep olive colour.

The salts with the brown oxide do not crystallize; they are brown, soluble in alcohol, and do not absorb nitric oxide.

The alkalies precipitate hydrated oxides from these solutions.

Iron and Chlorine unite in two proportions—the *chloride* may be obtained by evaporating green muriate of iron to dryness, and exposing the residuum to a red heat. A grey brittle substance is formed, consisting of one proportion of iron and two of chlorine 52 + 67.

When iron wire is heated in chlorine it burns with a red light, and produces a compound which rises in beautiful brown scales. It is the *perchloride of iron*,

and consists of one proportion of iron and three of chlorine 52 + 100,5. The chloride and perchloride of iron produce muriate and oxymuriate of iron when acted upon by water. These salts are both deliquescent and uncrystallizable.

Iodine and Iron readily form a brown compound, fusible at a red heat, and which, when put into water, forms a hydriodate of a green colour.

The *nitric acid* dissolves the protoxide and peroxide of iron, and produces a green nitrate and a red oxynitrate, neither of which are crystallizable.

Sulphur and Iron.—There are two sulphurets of iron—the black *sulphuret* is composed of 52 iron + 30 sulphur; and the yellow sulphuret, or *bisulphuret*, of 52 iron + 60 sulphur. The former compound is produced by melting sulphur with iron filings; it exists in nature under the name of magnetic pyrites—the bisulphuret is exclusively a natural product, very abundant, and called iron pyrites.

Sulphates of Iron.—The sulphuric acid with the protoxide of iron forms a salt which crystallizes in green rhomboidal prisms, of a styptic taste, soluble in twice their weight of cold water. This salt is called *Copperas* or *green vitriol*, and is often prepared by exposing roasted pyrites to moisture. It consists of one proportion of protoxide = 67 + two proportions of acid = 75. The *oxysulphate of iron* is obtained by dissolving the moist red oxide in dilute sulphuric acid—it does not crystallize, but affords, by evaporation, a red deliquescent mass, consisting of 1 oxide + 3 sulph. acid or 74,5 oxide + 112,5 sul. acid. It is formed in the mother waters of the sulphate.

Sulphuret of Iron may be formed by dropping phosphorus into a crucible containing red-hot iron wire; it is a brittle grey compound, and acts upon the magnet.

Phosphates of Iron.—These are both insoluble, and may be formed by adding solution of phosphate of soda to sulphate and oxysulphate of iron. The phosphate of iron is of a pale blue colour; the oxyphosphate is white.

Iron and Carbon.—The different kinds of cast iron contain more or less carbon, which materially affects their properties. Steel and plumbago are *carburets of iron*.

Carbonic Acid may be combined with the *protoxide of iron*, by adding carbonate of potash to sulphate of iron; a green precipitate of carbonate of iron falls, which, exposed to air, becomes brown, and evolves carbonic acid.

Hydrocyanic (Prussic) Acid may be united by double decomposition with the oxides of iron, as by adding the prussiate of potash to the sulphate and oxysulphate. The former affords a white, the latter a fine blue precipitate, of hydrocyanate or prussiate of iron. (*Prussian blue*.)

The alloys of iron, with the metals hitherto described, are not important.

Tin.

The native oxide is the principal ore of tin; the metal is obtained by heating it to redness with charcoal. Tin has a silvery white colour; it is malleable, though sparingly ductile. It melts at 440°,

Chemistry. and by exposure to heat and air is gradually converted into a white *peroxide*.

Protoxide of Tin is obtained by precipitating muriate of tin by ammonia; it falls in the state of hydrate; when dried, it is of a grey colour, and undecomposable by heat. It dissolves in the alkalies,—exposed to heat and air, it passes into the state of *peroxide*.

Peroxide of Tin is formed by treating the metal with nitric acid; there is a violent action attended by the formation of nitrate of ammonia. It dissolves in the alkalies, and hence some chemists have called it *stannic acid*. This is the *native oxide*.

The number representing tin is 55. The protoxide consists of 55 tin + 7,5 oxygen. The hydrate of 62,5 oxide + 8,5 water; and the peroxide of 55 tin + 15 oxygen.

Chloride of Tin is procured by heating together an amalgam of tin and calomel; it is a grey semi-transparent crystalline solid, which dissolves in water, forming a muriate of tin; it consists of 55 tin + 33,5 chlorine.

If tin be heated in chlorine, or if amalgam of tin be distilled with corrosive sublimate, a *bichloride* is obtained; it is a transparent colourless fluid, and when poured into water is instantly converted into oxymuriate of tin. It consists of 55 tin + 67 chlorine. It was formerly called Libavius's fuming liquor; it exhales fumes when exposed to a moist air, and produces muriatic acid and oxide of tin.

The muriate of tin used by dyers may be obtained by boiling one part of tin with two of muriatic acid. This solution quickly absorbs oxygen from the air and from several compounds, and if added to metallic solutions, revives or deoxidizes them. With solution of gold, it produces a purple precipitate used in painting porcelain. (*Purple of Cassius*.) It crystallizes in small deliquescent needles. With infusion of cochineal, it produces a crimson precipitate. The *oxymuriate of tin* (muriate containing the peroxide) may be formed by dissolving the metal in nitro-muriatic acid, or by adding water to the bichloride, or by exposing the muriate to air. It does not occasion precipitates in other metallic solutions, and produces a scarlet with cochineal.

Nitrate of Tin may be formed by acting upon the metal by dilute nitric acid, a yellow solution which will not crystallize is obtained,—exposed to air, it absorbs oxygen, and peroxide of tin precipitates.

Tin and Sulphur—There are two sulphurets of tin. That containing 1 proportion of metal + 1 of sulphur may be procured by heating tin with sulphur; it is of a bluish colour, and crystallizes in long needles. The *bisulphuret* is of a bright golden yellow colour, and flaky structure. (*Ausum musivum*.) It is formed by heating peroxide of tin with sulphur. These sulphurets consist respectively of 55 tin + 15 sulphur, and 55 tin + 30 sulphur.

Sulphate of Tin.—When tin is boiled in sulphuric acid, a solution is obtained which deposits white acicular crystals.

Hydrosulphuretted Oxide of Tin is yellow brown.

Many of the alloys of tin are useful. With copper it forms bronze, gun-metal, and bell-metal; and with iron, a white compound known under the name of *tin plate*.

Zinc.

Chemistry.

Zinc is found in the state of oxide and of sulphuret. It may be obtained pure by dissolving the zinc of commerce in dilute sulphuric acid, and immersing a plate of zinc for some hours in the solution, which is then filtered, decomposed by subcarbonate of potash, and the precipitate ignited with charcoal.

Zinc is a bluish white metal, malleable at 300°, but very brittle when its temperature approaches the point of fusion, which is about 680°.

Oxide of Zinc is obtained by heating the metal exposed to air. At a red heat it inflames, burns with a bright flame, and is converted into a white flocculent substance, formerly called *Pompholix nihil album*, and *Philosopher's wool*. It consists of 33 zinc and 7,5 oxygen. This oxide is white, tasteless, and soluble in the alkalies.

Chloride of Zinc is formed by heating leaf zinc in chlorine. It is a volatile fusible compound, producing a *muriate of zinc* by the action of water. It consists of 33 zinc + 33,5 chlorine.

Iodine and Zinc readily combine, and produce a fusible, volatile, and crystalline compound, which, when exposed to air, deliquesces into *hydriodate of zinc*.

Sulphuret of Zinc exists native under the name of *Blende*. It may be formed artificially by heating oxide of zinc with sulphur, and is then of a yellow brown colour. It consists of 33 zinc + 15 sulphur.

Sulphate of Zinc.—The metal is readily oxidized and dissolved by dilute sulphuric acid, hydrogen gas is given off, and a transparent colourless solution of sulphate of zinc results, which, by evaporation, affords crystals in the form of four-sided prisms, terminated by four-sided pyramids.

This salt is soluble in 2,5 parts of water at 60°. It consists of 1 proportion of oxide = 40,5 + 1 proportion of acid = 37,5. Its crystals contain 7 proportions of water = 59,5. Sulphate of zinc is prepared for the purposes of the arts from the native sulphuret, and is usually in the form of a white amorphous mass called *white vitriol*.

Phosphuret of Zinc is a brilliant lead-coloured compound.

Phosphate of Zinc is not crystallizable. It may be obtained by dissolving zinc in phosphoric acid and evaporation to dryness.

Carbonate of Zinc occurs native, forming one of the varieties of calamine.

Zinc forms with copper the very useful alloy called *brass*.

Manganese.

The common ore of manganese is the black or peroxide, which is found native in great abundance.

The metal may be procured by exposing the protoxide mixed with charcoal to an intense heat. It is of a bluish white colour, very brittle, and difficult of fusion. When exposed to air, it becomes an oxide.

Manganese and Oxygen.—There are two definite oxides of manganese. The *protoxide* may be obtained by digesting the native black oxide in muriatic acid. Chlorine is abundantly evolved, and the hydrogen of the muriatic acid unites with part of the oxygen of the oxide to produce water. The metal

Chemistry. thus partly deoxidized, is dissolved by the remaining muriatic acid, forming a *muriate of manganese*. Iron is almost always present, which may be easily separated by neutralizing the muriatic solution with ammonia. The oxide of iron is directly precipitated, but the oxide of manganese remains in solution, and may be separated by *excess* of ammonia.

The solutions of manganese furnish a white precipitate with the alkalies, which is a *hydrated oxide of manganese*, and which, when dried in close vessels, acquires a deep olive colour, and is the protoxide. It consists of 56,5 manganese + 15 oxy. and the hydrate contains 71,5 oxide + 17 water.

When this oxide is heated in contact with oxygen, it becomes deep brown, and is thus converted into the *peroxide*, which consists of 56,5 mang. + 22,5 oxygen. This peroxide is not soluble in acids.

Manganese and Chlorine.—By burning the metal in chlorine, or by exposing muriate of manganese to a strong heat, a pink semitransparent flaky substance is obtained, consisting of 56,5 M. + 67 C.

Manganese and Sulphur appear unsusceptible of combination.

Sulphate of Manganese is formed by dissolving the protoxide in the acid, or by boiling in it the peroxide, in which case oxygen is evolved. There are two sulphates. The one which is neutral is of a pink colour, the other, acid, is white. They crystallize in rhomboidal prisms.

Phosphuret of Manganese is of a blue white metallic lustre, and considerably inflammable.

Phosphate of Manganese is precipitated in the form of a white insoluble powder, by adding phosphate of soda to muriate of manganese.

Carbonate of Manganese is white, insipid, and insoluble in water.

Potassium.

The body known under the name of caustic potash is a hydrated oxide of this metal. It is decomposed at a white heat by the action of iron in the following manner: A sound and perfectly clean gun-barrel is bent, as shown in the annexed sketch. It

Fig. 1

Fig. 2.

is then covered with an infusible lute between the letters O and E (fig. 1.), and the interior of the luted part is filled with clean iron turnings. Pieces of fused potash are then loosely placed in the barrel between E and C. AA is a copper tube and small receiver which are adapted to the extremity O, and to each other, by grinding. This apparatus is next transferred to the furnace, arranged, as shown in fig. 2. X and T representing two glass tubes dipping into mercury. The furnace is supplied with air by a good double bellows entering at B, and a small wire basket (G) is suspended below the space E C. The part of the barrel in the furnace is now cautiously raised to a white heat, and the escape of air by the tube X shows that all is tight. Some burning charcoal is then put at the end (E) of the cage G, which causes a portion of potash to liquefy and fall into the low part of the barrel upon the iron. Hydrogen gas instantly escapes by the tube X, and attention must now be had to keep the copper tubes (AA) cool, by laying wet cloths upon them. When the evolution of gas ceases, fresh charcoal is placed under the potash, and so on till the whole has passed down; if too much potash be suffered to fall at once, the extrication of gas at X will be very violent, which should be avoided. If the space between A and O should become stopped by potassium, gas will issue by the tube T (which must always be under a greater pressure of quicksilver than the tube X), and it may be fused by applying hot charcoal to the tube, when the gas will again appear at X and cease at T. When the operation is concluded, the tubes X and T are removed, and corks quickly applied to the holes; and when the apparatus is cool, the barrel is carefully removed from the furnace, and a little naphtha suffered to run through the barrel. The potassium is found in globules in the tube and receiver AA, and considerable portions often lodge at O. The success of this operation is certain, if the heat has been sufficient; but the barrel, if not very carefully covered with lute, is apt to melt, and much, if not the whole, of the product is lost.*

Potassium is a white metal of great lustre. It instantly tarnishes by exposure to air. It is ductile and of the consistency of soft wax. At 150° it enters into perfect fusion; and at a bright red heat rises in vapour. At 32° it is a hard and brittle solid. If heated in air it burns with a brilliant white flame.

Potassium and Oxygen.—When potassium is thrown into water it instantly takes fire,—hydrogen gas is evolved, and oxide of potassium or potash is found dissolved in the water. The quantity of hydrogen evolved in this experiment, becomes the indicator of the proportion of oxygen which has been transferred to the metal; 100 parts of potassium are thus found to absorb 20 of oxygen; and if this be considered a protoxide, then 20 : 100 :: 7,5 : 37,5,—so that 37,5 will be the number representing potassium, and 37,5 P. + 7,5 O. = 45 will represent

* The discovery of the nature of the alkalies, the most brilliant of modern chemistry, was made by Sir H. Davy in the year 1807, and was the result of his laborious electro-chemical researches, of which the commencement and progress are detailed in his various communications to the Royal Society.

Chemistry. *dry oxide of potassium.* Potash in the state it is usually met with in laboratories, contains a considerable portion of water, from which it may be freed by the action of iron at high temperatures, and there always remains in the barrel, after the above experiment, a large portion of dry potash. It is a hard grey substance which, by water, is slowly converted into the hydrated oxide, or caustic potash, which may be obtained by evaporation to dryness. This substance, after exposure to a red heat, is white and very soluble in water; it may be considered as a compound of 1 proportion of protoxide of potassium = 45 + 1 proportion of water = 8,5, and its number = 53,5.

Peroxide of Potassium.—If the metal be heated in considerable excess of oxygen, it burns with intense heat and light, and an orange coloured substance is obtained, which consists of 37,5 potassium + 22,5 oxygen = 60. This peroxide of potassium, when put into water, effervesces, oxygen is given off, and a solution of the hydrated protoxide is obtained.

The *hydrated protoxide, or caustic potash*, is procured in our laboratories by decomposing its subcarbonate by lime. It is often cast into sticks for the use of surgeons, who employ it as a caustic, and in this state it generally contains some peroxide, and therefore evolves oxygen when dissolved in water. It may be further purified by the action of alcohol, which dissolves the pure hydrate, and leaves earthy and other impurities,—the alcohol is then driven off by heat.

Hydrate of Potassa thus purified is white,—very acrid and corrosive, and at a red heat evaporates in the form of white acrid smoke. It quickly absorbs moisture from the air, and at 60° one part of water dissolves two. It may be crystallized in octoëdrons.

Chlorine and Potassium act very energetically on each other, and produce the white compound which has been called *Muriate of Potash*, but which is a true chloride of potassium, consisting of 37,5 P. + 33,5 Ch. It is soluble without decomposition in three parts of water at 60°. When potassium is heated in gaseous muriatic acid, this compound is formed, and hydrogen is evolved.

Chlorate of Potash is formed by passing chlorine through a solution of potash. Chloride of potassium is one of the results, the other is a salt in brilliant rhomboidal tables (formerly called *Oxymuriate of Potash*), the chlorate. When exposed to heat it gives out oxygen, and chloride of potassium remains. It is soluble in 18 parts of cold and 2,5 of boiling water. It acts very energetically upon many inflammables, and triturated with sulphur, phosphorus, and charcoal, produces inflammation and explosion. It consists of one proportion of chloric acid and one of potash, or 71 C. A. + 45 P. Its ultimate components, therefore, are

6 proportions of oxygen,	}	= 45
5 in the acid and 1 in the alkali,		
1 proportion of chlorine, . . .		= 33,5
1 ————— potassium, . . .		= 37,5

Iode of Potassium.—Iodine and potassium act upon each other very energetically, and a crystalline compound is obtained, white, fusible. The hydriodic acid and potash produce a similar compound.

When iodine is put into solution of potash, the results are iodate of potash and iode of potassium.

Potassium and Hydrogen.—When potassium is heated in hydrogen, it absorbs a portion of the gas, and produces a grey and highly inflammable *hydru-rect*. When hydrogen and potassium are passed together through a white hot tube, the gas dissolves the metal, and produces a spontaneously inflammable *potassiu-rected hydrogen gas*. Both these compounds are usually formed, during the operation for obtaining potassium by the gun-barrel.

Nitrate of Potash—Nitre—Saltpetre.—This salt is an abundant natural product, and is principally brought to this country from the East Indies. It crystallizes in six-sided prisms, usually terminated by dihedral summits; it dissolves in 7 parts of water at 60°, and in its own weight at 212°. Its taste is cooling and peculiar. It consists of 1 proportion of acid = 50,5 + 1 proportion of potash = 45. Or of

1 ————— potassium, . . .		37,5

95,5

When exposed to a white heat, it is decomposed into oxygen, nitrogen, and potash. It fuses at a heat below redness, and congeals on cooling into cakes called *sal prunelle*. It is rapidly decomposed by charcoal at a red heat. The products of the combustion of a mixture of charcoal and nitre, are carbonic acid and nitrogen gases, and subcarbonate of potash. It is also decomposed by sulphur (see Sulphuric Acid), and by phosphorus.

This is a highly important salt, as constituting the basis of gunpowder. It is also largely employed as a source of nitric acid. (See Nitric Acid.)

Potassium unites to Sulphur with the evolution of much heat and light, and produces a red compound.

Potash and Sulphur, when fused together, form a red *sulphuret of potash*. (*Liver of Sulphur*.) Its taste is bitter and acrid. It is very soluble in water, forming a yellow solution of *hydrosulphuret of potash*. The action of the sulphuret of potash on water is complicated, and has been variously explained. By some this is considered as a compound of *potassium* and sulphur; in which case, when acted upon by water, hydrogen is imparted to the sulphur, and oxygen to the potassium; and a sulphuret of potash with excess of sulphur (or sulphuretted sulphuret of potash) is formed. If we consider the sulphuret as consisting of potash and sulphur, then the oxygen, as well as the hydrogen, of the water, must be transferred to the sulphur, and sulphuric and sulphurous acid, and sulphuretted hydrogen, would be formed; and generally when the solutions of the *livers of sulphur* are examined, sulphate and sulphite of the alkali are found. On the whole, however, it appears most probable, that when sulphur and the alkalies are fused together at a high temperature, the latter un-

Chemistry. dergo decomposition, and that sulphurets of their metallic bases are actually formed.

Sulphite of Potash is formed by passing sulphurous acid into a solution of potash, and evaporating out of the contact of air. Rhomboidal plates are obtained, white, of a sulphurous taste, and very soluble. By exposure to air, they pass into sulphate of potash.

Sulphate of Potash is the result of several chemical operations carried on upon a large scale in the processes of the arts. It may be formed directly by saturating sulphuric acid by potash. It crystallizes in short six-sided prisms, terminated by six-sided pyramids. The body of the prism is often wanting, and the triangular faced dodecaëdron results. This salt dissolves in 16 parts of cold, and 5 of boiling water. It consists of

$$\begin{array}{rcl} 1 \text{ proportion of acid} & = & 37,5 \\ 1 \text{ ————— alkali} & = & 45. \\ \hline & & 82,5 \end{array}$$

Supersulphate or Bisulphate of Potash is formed by adding sulphuric acid to a hot solution of sulphate of potash. The first crystals which form are in delicate needles of an acid taste, soluble in 2 parts of water at 60°, and consist of

$$\begin{array}{rcl} 2 \text{ proportions of acid} & = & 75. \\ 1 \text{ ————— potash} & = & 45. \\ \hline & & 120. \end{array}$$

Phosphuret of Potassium is a brown compound, which rapidly decomposes water, producing phosphuretted hydrogen gas, and hydrophosphuret of potash.

Phosphite of Potash is a soluble deliquescent uncrystallizable salt.

Phosphate of Potash is a soluble difficultly crystallizable salt. *Superphosphate* of potash crystallizes in four-sided prisms.

Potash and Carbonic Acid.—These bodies combine in two proportions, forming the *subcarbonate* and the *bicarbonate* of potash.

Subcarbonate of Potash is a salt of great importance in many arts and manufactures, and is known in commerce in different states of purity under the names of wood ash, potash, and pearl ash.

It may be obtained directly by passing carbonic acid into a solution of potash, evaporating to dryness, and exposing the dry mass to a red heat; or by burning *tartar*, whence the name *salt of tartar* has been applied to it. This salt is fusible without decomposition, at a red heat; it is very soluble in water, and deliquesces by exposure to air, forming a dense solution, once called *oil of tartar per deliquium*. Its taste is alkaline, and it renders vegetable blues green. It consists of

$$\begin{array}{rcl} 1 \text{ proportion acid} & = & 20,7 \\ 1 \text{ ————— potash} & = & 45 \\ \hline & & 65,7 \end{array}$$

Bicarbonate of Potash is formed by passing a current of carbonic acid into a solution of the subcarbonate. By evaporation crystals are obtained in the

Chemistry. form of four-sided prisms, with dihedral summits. Their taste is only slightly alkaline, and they require for solution 4 parts of water, at 60°. Exposed to a red heat, carbonic acid is evolved, and subcarbonate of potash remains. This bicarbonate consists of

$$\begin{array}{rcl} 2 \text{ proportions of carbonic acid} & = & 41,4 \\ 1 \text{ ————— potash} & = & 45. \\ \hline & & 86,4 \end{array}$$

Arsenate of Potash is formed by heating together white oxide of arsenic and nitrate of potash. It crystallizes in four sided prisms.

Chromate of Potash is obtained by digesting chromate of lead in a solution of potash. The salt crystallizes in rhomboidal prisms of a yellow colour.

Sodium.

Sodium is obtained from soda by an operation analogous to that for procuring potassium from potash. In colour it resembles lead, it fuses at 180°, and is volatile at a white heat. It burns when heated in contact with air, and requires the same cautions to preserve it as potassium.

Sodium and Oxygen.—When sodium is thrown upon water, it produces violent action, but the metal does not in general inflame; hydrogen is evolved, and a solution of soda is procured. By the quantity of hydrogen evolved, we learn that soda (*protoxide of sodium*) consists of about 74,6 sodium and 25,4 oxygen *per cent.*; and, if soda be considered as the protoxide, the number representing the metal will be 22, and soda will consist of 22 S. + 7,5 O., and be represented by 29,5. By heating sodium in oxygen, an orange-coloured oxide is formed, consisting of 22 S. + 11,25 O., and which, by the action of water, evolves oxygen, and produces a solution of the protoxide.

Soda, as it usually occurs in the laboratories, is obtained from the subcarbonate by the action of lime and alcohol, as described under the head *Potash*. It consists of 29,5 oxide of sodium + 8,5 water, and is represented by 38. When soda is exposed to air, it soon becomes covered with an efflorescence of subcarbonate of soda.

Chloride of Sodium.—Sodium, when heated in chlorine, burns, and produces a white compound, of a pure saline flavour, soluble in 2½ parts of water at 60°, and forming cubic crystals. It has all the properties of *common salt*, or *muriate of soda*, and consists of

$$\begin{array}{rcl} 1 \text{ proportion of chlorine} & = & 33,5 \\ \text{————— sodium} & = & 22, \\ \hline & & 55,5 \end{array}$$

This compound is decomposed, when heated with potassium. Sodium and chloride of potassium are the results.

When soda is heated in chlorine, oxygen is evolved; when heated in muriatic acid, water is formed; and in both cases chloride of sodium is the product.

Sodium and Iodine act upon each other with the same phenomena as potassium.

Chemistry. Nitrate of Soda crystallizes in rhombs, soluble in three parts of water at 60°.

Sulphuret of Sodium and of Soda. (See Potassium.)

Sulphite of Soda is crystallizable in transparent four and six sided prisms, soluble in four parts of water at 60°.

Sulphate of Soda—Glauber's Salt—is abundantly produced in the manufacture of muriatic acid by the action of sulphuric acid upon common salt.

Common salt consists of 22 sodium + 33,5 chlorine. Sulphuric acid consists of 37,5 dry acid + 8,5 water. The water of the acid, consisting of 1 hydrogen + 7,5 oxygen, is decomposed. Its hydrogen is transferred to the chlorine to produce gaseous muriatic acid (= 1 H. + 33,5 Cl. = 34,5 Mur. A.), and its oxygen unites to the sodium, forming dry soda (= 7,5 Ox. + 22 S. = 29,5 soda). The 37,5 dry acid then unite to the 29,5 soda, to produce sulphate of soda, which will be represented by the number 67. Sulphate of soda crystallizes from its aqueous solution in large four-sided prisms transparent, and efflorescent, when exposed to air. They consist of 67 dry sulphate + 85 water.

Phosphate of Soda crystallizes in rhomboidal prisms, soluble in three parts of water at 60°, and efflorescing when exposed. It consists of

29,5 soda.
25 phosphoric acid.

54,5

Subcarbonate of Soda is chiefly obtained by the combustion of marine plants. It consists of

29,5 soda.
20,7 carbonic acid.

50,2

Its crystals contain 7 proportions of water = 59,5, which may be expelled by heat. They effloresce by exposure to air.

Bicarbonate of Soda is formed by passing carbonic acid through the solution of the subcarbonate. By evaporation, a crystalline mass is obtained. This salt consists of

29,5 soda.
41,4 carbonic acid.

70,9

Barium.

To obtain this metal, the earth baryta is negatively electrized in contact with mercury; an amalgam is gradually formed, from which the mercury may be expelled by heat, and the metal barium remains, appearing, according to Sir H. Davy, of a dark grey colour, and being more than twice as heavy as water. It greedily absorbs oxygen, and burns with a deep red light when gently heated, producing the oxide of barium.

Oxide of Barium, or baryta, is obtained by exposing the nitrate of baryta to a bright red heat. It is of a grey colour, and very difficult of fusion, and

Chemistry. appears to consist of 65 barium + 7,5 oxygen, and is consequently represented by 72,5. It eagerly absorbs water, heat is evolved, and a white solid is formed, containing about 10 per cent. of water; this is the hydrate of baryta, and may be considered as a compound of 1 proportion of baryta = 72,5 + 1 proportion of water = 8,5, and is consequently represented by 81.

This hydrate dissolves in boiling water; and, as the solution cools, deposits flattened hexagonal prisms, which contain a large quantity of water.

Baryta, like the alkalies, converts vegetable blues to green, and serves as an intermede between oil and water, whence it has been called an alkaline earth.

It exists in two natural combinations only,—namely, as sulphate and carbonate. According to M. Gay-Lussac, there is a peroxide of barium obtained by heating baryta in oxygen.

Chloride of Barium may be obtained by heating baryta in chlorine, in which case oxygen is evolved; or more easily by dissolving carbonate of baryta in diluted muriatic acid. By evaporation, tabular crystals are obtained, soluble in five parts of water at 60°; and consisting, when dry, of 65 barium + 33,5 chlorine = 98,5.

Chlorate of Baryta is formed in the same way as chlorate of potash. It crystallizes in quadrangular prisms, soluble in four parts of water, at 60°. It consists of

1 proportion of baryta = 72,5
1 chloric acid = 71,

143,5

Or of 1 proportion of barium = 65,
6 ——— of oxygen = 45,
1 ——— of chlorine = 33,5

143,5.

Gay-Lussac procured chloric acid by the action of sulphuric acid upon this salt.

Iodate of Baryta is a very difficultly soluble compound—the hydriodate is crystallizable and very soluble.

Nitrate of Baryta crystallizes in octoedrons; it is soluble in 12 parts of cold and 4 of boiling water; it is decomposed by heat, furnishing pure baryta.

It consists of 72,5 baryta,
50,5 nitric acid.

123.

Sulphuret of Barium and Phosphuret of Barium are brown compounds, which act upon water, as already described, producing hydrosulphuret and hydrophosphuret of baryta.

Sulphate of Baryta is an abundant natural product; it is insoluble, and therefore produced whenever sulphuric acid or a soluble sulphate is added to any soluble salt of baryta. Hence the solutions of baryta are accurate tests of the presence of sulphuric acid. They are all highly poisonous, and sulphate of soda, or dilute sulphuric acid, are the best anti-

Chemistry. notes. Sulphate of barytes consists of one proportion of sulphuric acid and one of baryta.

37,5 sul. a.
72,5 baryta.

110.

Phosphate of Barytes consists of

25 phosphoric acid.
72,5 baryta.

97,5

It is insoluble in water, and therefore formed by adding a solution of phosphoric acid or phosphate of soda to nitrate or muriate of baryta.

Carbonate of Baryta is found native. Artificially produced it is a white compound insoluble in water, containing 20,7 carb. acid.

72,5 baryta.

93,2

Strontium

Is procured from the earth strontia by the same process as barium, which metal it resembles in appearance.

Oxide of Strontium, or the earth *Strontia*, is procured by the ignition of the pure nitrate; it is of a grey colour; it forms a pulverulent, and a crystallized hydrate. It consists of 44,5 strontium.

7,5 oxygen.

The pulverulent hydrate contains 52 strontia.
8,5 water.

60,5

Strontia and its soluble compounds are not poisonous; they tinge the flame of alcohol blood-red, while the corresponding compounds of baryta give it a yellow tint.

Chlorine and Strontium.—This compound, which has also been called Muriate of Strontia, is commonly procured by dissolving carbonate of strontia in muriatic acid. It crystallizes in slender six-sided prisms, soluble in twice their weight of water at 60°. When chlorine is made to act upon strontia, it is absorbed, and oxygen evolved. The resulting compound contains 44,5 strontium.

33,5 chlorine.

78

Nitrate of Strontia crystallizes in octoëdra; it is soluble in its weight of water at 60°. It consists of

52 strontia.
50,5 nitric acid.

102,5

Sulphate of Strontia occurs native. It is nearly insoluble, 1 part requiring 4000 of water for its solution. When heated with charcoal, its acid is de-

composed, and sulphuret of strontia is formed, which affords nitrate by the action of nitric acid. This process, equally practicable upon sulphate of baryta, is sometimes adopted to obtain the earth. Sulphate of strontia contains 52 strontia.

37,5 acid.

89,5

Phosphate of Strontia is an insoluble white salt, containing

52 strontia.
25 acid.

77

Carbonate of Strontia exists native. Artificially formed, it is a white insoluble body, containing

52 strontia.
20,7 carbonic acid.

72,7

Calcium

When lime is electrized negatively in contact with mercury, an amalgam is obtained, which, by distillation, affords a white metal. It has been called *calcium*, and, when exposed to air, and gently heated, it burns, and produces the *oxide of calcium*, or lime.

Lime appears to consist of 19 parts of this metallic base united to 7,5 parts of oxygen, so that its representative number will be = 26,5. The combinations of lime are very abundant natural products, and of these the native carbonate, which, more or less pure, constitutes the different kinds of marble, chalk, and limestone, and which is also the leading hardening principle of shell, coral, &c. may be considered as the most important.

Pure lime may be obtained by exposing powdered white marble to a white heat. Its colour is grey, it is acrid and caustic, and converts vegetable blues to green; its specific gravity is 2,3, it is very difficult of fusion. Exposed to air it becomes white by the absorption of water and a little carbonic acid. When thrown into water, a considerable rise of temperature ensues. At the temperature of 60°, 750 parts of water are required for the solution of one part of lime.

Chloride of Calcium is produced by heating lime in chlorine, in which case oxygen is evolved; or by evaporating muriate of lime to dryness, and exposing the dry mass to a red heat in close vessels. It consists of 19 calcium + 33,5 chlorine = 52,5. This compound has a strong attraction for water, it deliquesces when exposed to air, and is difficultly crystallizable from its aqueous solutions.

Iodate of Lime is difficultly crystallizable in small quadrangular prisms.

Hydriodate of Lime is very deliquescent; when dried, it becomes *Iode of Calcium*, a white fusible compound.

Nitrate of Lime is a deliquescent salt soluble in 4 parts of water at 60°. It is found in old plaster and mortar, from the washings of which nitre is pro-

Chemistry. cured by the addition of subcarbonate of potash. It is composed of

Lime, 26,5
Nitric acid, 50,5

77

Sulphuret of Lime is formed by heating lime with sulphur. It is soluble in water with the same phenomena as sulphuret of potash.

Sulphate of Lime occurs native in selenite, gypsum; and plaster stone. It is easily formed artificially, and then affords silky crystals soluble in 350 parts of water. When these or the native crystallized sulphate are exposed to a red heat, they lose water, and fall into a white powder (plaster of Paris), which, made into a paste with water, soon solidifies. Dry sulphate of lime consists of

26,5 lime,
37,5 sulph. acid.

64

Crystalline selenite contains two proportions of water, and is consequently represented by $64 + 17$, or 81. As sulphate of lime is more soluble in water than pure lime, sulphuric acid affords no precipitate when added to lime-water. Nearly all spring and river water contains this salt, and in those waters which are called *hard* it is abundant.

Phosphuret of Lime.—By passing phosphorus over red-hot lime, a brown compound is produced, which rapidly decomposes water with the evolution of phosphuretted hydrogen gas. Hydrophosphuret and phosphate of lime are also formed.

Phosphate of Lime exists abundantly in the bones of animals; it is also found in the mineral world. It may be formed artificially, by mixing solutions of phosphate of soda and of lime. It is insipid and insoluble, but dissolves in dilute nitric and muriatic acid without decomposition. It is decomposed by sulphuric acid, and thus the phosphoric acid for the production of phosphorus is usually procured. It consists of

26,5 lime,
25 phosphoric acid.

51,5

Superphosphate of Lime may be obtained by dissolving the phosphate in phosphoric acid; by evaporation, it affords small crystalline laminæ.

Carbonate of Lime is the most abundant compound of this earth. When lime-water is exposed to air, it becomes covered with an insoluble film of carbonate of lime, and hence is an excellent test of the presence of carbonic acid. But excess of carbonic acid redissolves the precipitate, producing a supercarbonate. Carbonate of lime is precipitated by the carbonated alkalies from solutions of muriate and nitrate of lime. Exposed to a red heat the carbonic acid escapes, and *quicklime* is obtained.

It consists of 26,5 lime,
20,7 carbonic acid.

47,2

Fluor Spar.—*Fluate of Lime*.—These terms have been applied to a body containing a peculiar principle which has not hitherto been obtained in an insulated state.

It is a principle which probably belongs to the acidifying supporters of combustion, and which in fluor spar is perhaps united to calcium. It appears to be united with hydrogen in the *fluoric*, or *hydrofluoric* acid. This supposed base has been called *fluorine* by Sir H. Davy; and *phlore* (from *φθορος*, destructive), by M. Ampère.

Hydrofluoric acid (hydrophoric) is procured by distilling a mixture of one part of the purest fluor spar in fine powder with two of sulphuric acid; the distillatory apparatus and receiver should be of lead or silver; the heat required is not considerable; sulphate of lime remains in the retort; and a highly acrid and corrosive liquid passes over, which requires the assistance of ice for its condensation. This acid is colourless, of a very pungent smell, and extremely destructive. If applied to the skin, it instantly kills the part, produces extreme pain, and extensive ulceration. At 80° it becomes gaseous; it has never been frozen; it produces white fumes when exposed to a moist air. This acid acts upon potassium and sodium, and some other metals, with great energy; hydrogen is evolved, and a peculiar compound, probably of the basis of the acid and of the metal, results. These compounds might be called *fluorides*.

Fluoboric Acid.—This is probably a compound of fluorine with boron. It is gaseous, and may be obtained by heating in a glass retort twelve parts of sulphuric acid with a mixture of one part of fused boracic acid, and two of fluuate of lime reduced to a very fine powder. The gas must be received over mercury: 100 cubical inches weigh 73,5 grains; so that the specific gravity of fluoboric acid, compared with hydrogen, is 32,68; and, with atmospheric air, 2,371. It produces very copious fumes when suffered to escape into a moist atmosphere; and, when acted upon by water which dissolves 700 times its volume, it affords a solution of hydrofluoric and boracic acids, whence it would seem that the hydrogen is transferred to the fluorine, and the oxygen to the boron. It acts with great energy on vegetable and animal bodies, depriving them of moisture and hydrogen.

Magnium.

The metallic base of magnesia has not hitherto been obtained; but, when that earth is negatively electrized with mercury, the resulting compound decomposes water, and gives rise to the formation of *magnesia*.

Magnesia, or *Oxide of Magnium*—is concluded, from indirect experiments, to consist of 11 metal + 7,5 oxygen; its representative number, therefore, is 18,5. Magnesia is a white insipid substance, which slightly greens the blue of violets. Its specific gravity is 2,3; it is almost infusible and insoluble in water.

Chloride of Magnium may be obtained by passing chlorine over red-hot magnesia; oxygen is expelled, and a substance obtained which moisture converts into muriate of magnesia.

Chemistry.

Muriate of Magnesia is very deliquescent, and difficultly crystallized. Its solution has a bitter saline taste. Exposed to heat, muriatic acid flies off, and the magnesia remains pure. It consists of

Magnesia, 18,5
Muriatic acid, 84,5

53

Chloride of Magnesia is a bitter deliquescent salt. *Hydriodate of Magnesia* is deliquescent, and loses hydriodic acid by exposure to heat.

Nitrate of Magnesia crystallizes in rhomboidal prisms, deliquescent and soluble in half its weight of water. It contains

Magnesia, 16,5
Nitric acid, 50,5

69

Sulphate of Magnesia is a commonly occurring compound of this earth, much used in medicine as an aperient. It is largely consumed in the preparation of carbonate of magnesia. It crystallizes in four-sided prisms with reversed dihedral summits, or four-sided pyramids. Its taste is bitter. It is soluble in its own weight of water at 60°. When exposed to a red heat, it loses its water of crystallization, amounting to about 50 per cent., but is not decomposed. It consists of

Magnesia, 18,5
Sulphuric acid, 37,5

56

In its crystallized state, it may be considered as composed of 1 proportion of dry sulphate + 7 proportions of water,

Or, 56 Sulphate,
59,5 Water.

115,5 •

This salt is usually obtained from sea-water, occasionally from saline springs, and sometimes by the action of sulphuric acid on magnesian limestones.

Carbonate of Magnesia is generally procured by adding carbonated alkalies to a solution of sulphate of magnesia. It is a white, insipid, and insoluble powder, which loses its acid at a red heat, and thus affords pure (calcined) magnesia. It contains

18,5 Magnesia,
20,7 Carbonic acid.

39,2

It is soluble in excess of carbonic acid, and this solution affords crystals of bicarbonate, containing

18,5 Magnesia,
41,4 Carbonic acid.

59,9

Silicium.

Chemistry.

It has been assumed that the earth silica consists of a metallic basis, united with oxygen, and that it contains 50 per cent. of each of its components; so that, if the earth be considered a deutoxide, it will consist of

15 Silicium,
15 Oxygen.

30

Oxide of Silicium, Silica, or Siliceous Earth—is a very abundant natural product. It exists pure in rock-crystal, and nearly pure in flint. Its colour is white; its specific gravity 2,66. It fuses at a very high temperature. In its ordinary state it is insoluble in water; but it dissolves in very minute portions in that fluid, when recently precipitated in the form of hydrate; and in the same state it dissolves in the acids. It readily unites with the fixed alkalies, and forms glass; or, if the alkali be in excess, a liquid solution of the earth may be obtained, whence it is precipitated in the state of a gelatinous hydrate by acids.

The only body which acts energetically upon silica is the hydrofluoric acid. The result of this action is a gaseous compound, which has been called *silicated fluoric acid*; it is probably a compound of silicium and fluorine. To obtain this gas, three parts of fluor spar, and one of silica finely powdered, are mixed in a retort with an equal weight of sulphuric acid; a gentle heat is applied, and the gas evolved is to be collected over mercury.

Silicated fluoric acid is a colourless gas; its odour is acrid, much resembling muriatic acid; its taste very sour; its specific gravity 3,574 to air; 100 cubic inches = 110,78 grains, so that its specific gravity to hydrogen is 4,92. It extinguishes burning bodies. It produces white fumes when in contact with damp air, and when exposed to water, a little hydrogen is evolved, and two compounds of silica with fluoric acid are formed; the one *acid*, and dissolved in the water, the other containing excess of earth, and insoluble. The dry gas contains 62 per cent. of silica; the aqueous solution only retains 55 per cent. Water dissolves 260 times its bulk of this gas. When one volume of silicated fluoric acid is mixed with two of ammonia, a total condensation ensues, and a dry *silica fluete of ammonia* results. Potassium, when heated in this gas, burns and produces a brown compound, which, when dissolved in water, affords *fluete of potash*. The uses of silica are numerous and important; it forms an ingredient in pottery and porcelain, and with alkali it forms glass. It appears from the experiments of Mr J. F. Daniell, that silicium exists in some of the varieties of cast iron. (*Journal of Science and Arts*, Vol. II.)

Alumium.

The earth alumina constitutes some of the hardest gems, such as the sapphire and ruby, and it gives a peculiar softness and plasticity to some earthy compounds, such as the different kinds of clay. It is analogically considered as a metallic oxide.

Chemistry.

To obtain pure alumina we add carbonate of potash to a solution of alum, and ignite the precipitate; it is a tasteless white substance, forming a cohesive mass with water, and retaining water even at a red heat; its specific gravity is 2; it is soluble in soda and potash; and forms compounds with baryta, strontia, lime, and silica. It is an essential ingredient in pottery and porcelain.

One of its saline combinations is of important use in the arts, namely alum; a triple sulphate of alumina and potash. This salt is usually prepared by roasting and lixiviating certain clays containing pyrites; to the lyes, a certain quantity of potash is added, and the triple salt is obtained by crystallization.

Alum has a sweetish astringent taste. It dissolves in five parts of water at 60°, and the solution reddens blues. It furnishes octoëdral crystals. When heated, it loses water of crystallization, and a part of its acid, and becomes a white spongy mass. In its crystalline form, it consists of

Sulphuric acid,	-	33
Alumina,	-	12
Potash,	-	9
Water,	-	46

100

When alum is ignited with charcoal, a spontaneously inflammable compound results, which has long been known under the name of Homberg's pyrophorus. The potash is decomposed in this process,

along with the acid of the alum, and pyrophorus is a compound of sulphur, charcoal, and potassium, with alumina.

Zirconium.

The earth *zircon*, or the oxide of zirconium, is a white insipid substance; specific gravity 4,8; it is found in the zircon of Ceylon; it is characterized by insolubility in pure alcalies, but is soluble in alkaline carbonates. Its combinations with the acids are of difficult solubility or insoluble, and have been very little inquired into.

Yttrium.

The earth *yttria* derives its name from Yttertz in Sweden; it is found in the mineral called *gadolinite*. It is white and tasteless; its specific gravity = 4,84. It is insoluble in the caustic alcalies, but dissolves sparingly in carbonate of ammonia. Its saline combinations have been scarcely examined.

Glucium.

The earth *glucine* was discovered by Vauquelin in the beryl; it also exists in the emerald of Peru; it is white and insipid; its specific gravity = 2,97. It dissolves in caustic potash, and soda, and thus resembles alumine, but differs from yttria. Again, it differs from alumine, but resembles yttria in being soluble in carbonate of ammonia; it is much more soluble in this solution than yttria. With the acids it forms saline compounds of a sweetish astringent taste.

TABLE

Exhibiting the Specific Gravities and Representative Numbers of the Metals, and of their Combinations; with the General and Distinctive Characters of the Metallic Salts.

SUBSTANCES.	Specific Gravity.	Representative Number.	Composition.	REMARKS.
<i>METALS of FIRST CLASS.</i>				
Gold	19,30	97		The salts of gold are yellow and soluble in water. Potash and soda produce in them yellow precipitates. Sulphuretted hydrogen and hydrosulphuret of ammonia occasion black precipitates, phosphuretted hydrogen, a purple precipitate, a plate of tin or muriate of tin, a purple powder. Sulphate of iron separates minutely divided metallic gold. Tincture of galls gives a brown precipitate. Triple prussiate of potash occasions no precipitate.
peroxide		104,5	97 G. + 7,5 ox.	
chloride		130,5	97 G. + 33,5 C.	
muriate		139	104,5 ox. G. + 34,5 M. A.	
chlorate				
iodide				
hydriodate				
nitrate		155	104,5 ox. G. + 50,5 N. A.	
sulphuret		127	97 G. + 30 S.	
sulphite				
sulphate				
hydrosulphuret				
phosphuret		117	97 G. + 20 P.	
phosphite				
phosphate				
Hydriodic acid produces an insoluble yellow precipitate in dilute muriate of gold, which is the iode of gold. Heat separates the iodine.				
Sulph. acid produces a metallic precipitate in solution of gold.				
Neither these acids, nor their neutral salts, occasion any precipitate in solution of muriate of gold.				

SUBSTANCES.	Specific Gravity.	Representative Number.	Composition.	REMARKS.
Gold hydrophosphuret				
— carbonate				
— cyanuret				
— prussiate				
— borate				
Silver	10,50	102		The salts of silver are reduced upon charcoal by the blow-pipe. The soluble salts are precipitated by the alkalies, which furnish dark olive precipitates; by sulphuretted hydrogen and hydrosulphuret of ammonia, nearly black; by infusion of galls, yellow brown; by prussiate of potash and iron, white. Muriatic acid and the muriates give white precipitates of chloride of silver. Sulphate of iron, and a plate of copper, throw down metallic silver.
— oxide		109,5	102 S. + 7,5 ox.	
— chloride		135,5	102 S. + 33,5 C.	
— muriate				
— chlorate				
— iode				
— hydriodate

— borate				
Platinum	21	92		The solutions of these salts are deep or brownish yellow. They afford no precipitate with solutions of soda, of sulphate of iron, or of prussiate of potash. The addition of the latter produces a fine green solution. Potash and ammonia, and many of their salts, occasion yellow precipitates. Sulphuretted hydrogen occasions a black precipitate. Infusion of galls gives a dingy precipitate.
— protoxide		99,5	92 P. + 7,5 O.

— prussiate				
Palladium	11,50			The Salts of Palladium are precipitated by sulphate of iron; also brown by sulphuretted hydrogen; black by muriate of tin; greenish brown by prussiate of potash; deep orange by sulphate and nitrate of potash.
— oxide				
Rhodium				•The Salts of Rhodium are not

Chemistry.

Chemistry.

SUBSTANCES.	Specific Gravity.	Representative Number.	Composition.	REMARKS.
Rhodium oxide . . .				precipitated by muriate of ammonia, hydrosulphuret of ammonia, prussiate of potash, or alkaline carbonates. The caustic alkalies occasion a yellow precipitate. The salts of iridium are soluble in water, and generally of a blue colour.
Iridium . . .				
— oxide . . .				
METALS of SECOND CLASS.				
Osmium . . .				The Mercurial Salts are volatilized by heat. They are precipitated yellowish by prussiate of potash; deep brown by hydrosulphuret of ammonia and copper separates pure mercury. The salts, with the protoxide, furnish black precipitates with the alkalies, and white with muriatic acid. The salts with the peroxide furnish to the fixed alkalies reddish precipitates, and white with ammonia.
— oxide . . .

METALS of THIRD CLASS.				
Arsenic . . .	8,35	45		Hydriodic Acid produces a precipitate of white oxide of arsenic, when added to arsenite of potash, and hydriodate of potash is formed. Arsenite of potash gives a white precipitate, with hydrosulphuret of ammonia; a white precipitate soon becoming yellow and brown with nitrate of silver; a grey precipitate with nitrate, and a white with oxynitrate of mercury; a white with nitrate of lead; a pale green with nitrate of nickel; pale pink by nitrate of cobalt; apple green with nitrate of copper; white with the muriate and oxymuriate of tin; dingy green with the muriate and oxymuriate of iron; white with sulphate of zinc; bright yellow with nitrate of uranium. The Arseniate of Potash produces a reddish precipitate in nitrate of silver; straw-coloured with nitrate, and yellow with oxynitrate of mercury; white with nitrate of lead; pale green with nitrate of nickel; pale blue with nitrate of copper; pink with nitrate of cobalt; white with muriate of tin; no precipitate with oxymuriate of tin; pale sea-green with muriate and oxymuriate of iron; straw colour with nitrate of uranium; and white with sulphate of zinc. The compounds of the arsenic and arsenious acids are decomposed when heated with charcoal, and exhale an alliaceous smell. Chromic Acid and Chromate of Soda produce insoluble precipitates in solutions of silver, mercury, lead, copper, iron, and uranium; the colours are crimson, red, yellow or orange, apple green, brown, and yellow. No precipitate is formed in solutions of nickel, zinc, tin, cobalt, gold, or platinum.

Chemistry.

Chemistry.

SUBSTANCES.	Specific Gravity.	Representative Number.	Composition.	REMARKS.
Antimony	6,70	85		The soluble binary salts of the protoxide of antimony are precipitated white by water; the precipitate is a subsalt. Sulphuretted hydrogen, and hydrosulphuret of ammonia, give an orange precipitate, and a plate of iron or zinc throws down the metal in the form of a black powder.
1. oxide		100	85 A. + 15 O.	
2. oxide		107,5	85 A. + 22,5 O.	
chloride		152	85 A. + 67 C.	
muriate				
iodide				
sulphuret		115	85 A. + 30 S.	
sulphate				
hydrosulphuret				
phosphuret				
phosphate				
Uranium	9			Of the Salts of Uranium the greater number are soluble, and of a greenish yellow colour, they form yellow precipitates with the alkalies, and afford a reddish yellow iode with hydriodic acid. Prussiate of potash forms a precipitate of a rich brown colour, and hydrosulphuret of ammonia one nearly black.
oxide				
Cerium		86		Nearly all the Salts of Cobalt are of a red colour; potash, soda, and ammonia, produce in them blue precipitates of hydrated oxide, which is soluble in excess of ammonia, producing a red solution. Hydrosulphuret of ammonia gives a black precipitate. Prussiate of potash a pale green. Carbonates, phosphates, and arseniates, produce red precipitates. Hydriodic acid does not precipitate the salts of cobalt.
1. oxide		101	86 C. + 15 O.	
2. oxide		108,5	86 C. + 22,5 O.

The salts of magnesia are not precipitated by a solution of bicarbonate of potash (cold), nor by subcarbonate of ammonia but if heat be applied, carbonic acid escapes, and the earth is precipitated in the state of subcarbonate. The salts of magnesia are only partially decomposed by ammonia, which forms triple salts with the earth and acid. Oxalate of ammonia does not precipitate magnesia.

PART IV.

VEGETABLE CHEMISTRY.

This part of the science relates to the chemical changes which are observed during the germination and growth of plants; to the composition of vegetable substances; and to the phenomena and products of fermentation.

The seeds of plants consist of three distinct parts. 1. The exterior coat or membrane. 2. The cotyledons, which form the bulk of the seed. 3. The germ.

When a seed is placed under favourable circumstances for germination, the exterior coat bursts from the swelling of the cotyledons—the germ increases in size—it puts forth a *radicle*, which soon becomes a perfect root, and a *plumula* which forms the stem and leaves.

A due temperature, generally between 50° and 70°, a proper supply of moisture and access of air, are the essential requisites for perfect germination.

The oxygen of the atmosphere abstracts carbon from the principles of the cotyledons, by which saccharine matter is formed; this is absorbed by the vessels which, arising from the young germ, ramify through them, and tends to nourish the young plant until its roots are fit for their functions. Water is obviously required in these changes, which terminate in producing a plant with a root, stem, and leaves.

The leaves of plants, when exposed to the sun's rays, absorb carbonic acid from the atmosphere, and evolve oxygen. If healthy leaves, gathered on a warm dry day, be placed under a jar of air, it will be found that, during the night, those which are thick and fleshy absorb a portion of oxygen, while those which are thin and delicate absorb also oxygen, and evolve a portion of carbonic acid; which, upon exposure to the sun, they again decompose and restore the oxygen: So that thick leaves diminish the bulk of the air to which they are exposed during the night,

and increase it in the day. M. de Saussure found the leaves of the *Cactus opuntia* especially adapted for these experiments. It is only the green parts of plants that exhibit these properties. The roots, wood, and flowers, simply evolve a small portion of carbonic acid. From manures and the soil plants absorb small quantities of saline and carbonaceous matter. The salts most commonly found in vegetables are carbonate, sulphate, and phosphate of potash, carbonate and phosphate of lime, phosphate of magnesia. We also find the chlorides of potassium and sodium, the oxides of iron and manganese, and silica.

Vegetable substances may be considered as consisting of **ULTIMATE** and **PROXIMATE PRINCIPLES**. Of the *ultimate principles* the most important are *Oxygen*, *Hydrogen*, *Carbon*, and *Nitrogen*. The three first exist in all vegetable bodies—the latter is confined to a few. To exhibit these elements, a vegetable substance, starch for instance, may be put into a small earthen retort, to which an earthen tube is attached, passing through a furnace, and slightly inclined. To the other extremity of this tube is annexed a receiver, whence a bent glass tube issues to convey the gaseous products to the mercurial trough. The earthen tube is heated to redness, and afterwards the retort is gradually raised to the same temperature—the starch is thus decomposed, and affords charcoal and water, carbonic oxide and acid, and carburetted hydrogen. Sometimes a little empyreumatic oil and acetic acid are formed, and if the vegetable contain nitrogen, there is more or less ammonia produced.

The *proximate principles* of vegetables may be arranged under four divisions, founded upon the nature and proportions of their ultimate components. In the first division are comprised those in which the relative proportion of the oxygen to the hydrogen is greater than in water. In the second, those in which the relative proportions of oxygen to hydrogen are the same as in water; in the third, those in which

Chemistry. there is excess of hydrogen; in the fourth, those which contain nitrogen.

The bodies contained in the first division are all acid, and as they are described in the Article CHEMISTRY of the *Encyclopædia*, it will here only be required to enumerate them.

1. *Acetic acid*, composed of

Carbon,	50,224
Oxygen and hydrogen in the } proportions of water,	46,911
Excess of oxygen,	2,865
	<hr/> 100,000

2. *Oxalic Acid*, containing

Carbon,	26,566
Oxygen and hydrogen in the } proportions of water,	22,872
Excess of oxygen,	50,562
	<hr/> 100,000

3. *Citric Acid*, containing

Carbon,	33,811
Oxygen and hydrogen as in } water,	52,749
Excess of oxygen,	13,440
	<hr/> 100,000

4. *Tartaric Acid*, consisting of

Carbon,	24,050
Oxygen and hydrogen as in } water,	55,240
Excess of oxygen,	20,710
	<hr/> 100,000

5. *Benzoic Acid*.

6. *Camphoric Acid*.

7. *Galic Acid*.

8. *Malic Acid*.

9. *Suberic Acid*.

10. *Succinic Acid*.

11. *Mellitic Acid*.

12. *Saccharic Acid*.

To these the following have been lately added :

13. *Fungic Acid*. Discovered in certain fungi by M. Braconnot. It is deliquescent, uncrystallizable, colourless, and of a very sharp flavour. It forms with baryta a difficultly crystallizable salt, soluble in 15 parts of water at 60°; with potash and soda uncrystallizable deliquescent salts, insoluble in alcohol; with oxide of zinc a crystallizable salt. Added to acetate of lead it produces a white flocculent precipitate, soluble in distilled vinegar. (See *Annales de Chimie*, tom. 87.)

14. *Kinic Acid*, found in combination with lime in cinchona bark. (Vauquelin, *Annales de Chimie*, tom. 59.)

The law of definite proportions, as applied to salts of vegetable acids, has not been sufficiently investigated.

The substances of the second division contain oxygen and hydrogen, in the same relative proportions as in water. All these bodies are solid, heavier than water, inodorous, and without action on vegetable colours. Their properties are described in the *Encyclopædia* (Art. CHEMISTRY). They are, 1. *Sugar*. 2. *Gum*. 3. *Starch*. Iodine is an excellent test for starch. It produces a deep blue colour when added to its solutions. 4. *Lignin*.* 5. *Tannin*. (See Mr Hatchett's papers on this subject, *Phil. Trans.* 1805.) 6. *Extractive*.

The third division contains bodies with excess of hydrogen; they generally abound in carbon, and are insoluble, or sparingly soluble in water. They are, 1. *Fixed Oil*. 2. *Volatile Oil*. 3. *Resin*. 4. *Caoutchouc*. 5. *Camphor*. 6. *Wax*.†

The fourth division contains one substance only, namely *Gluten*; which, when submitted to destructive distillation, affords products analogous to those of animal matter, and especially characterized by ammonia.

Besides the bodies which are comprehended in

* MM. Gay-Lussac and Thenard have concluded, from their experiments on the wood of the oak and the beech, that 100 parts of the first contains :

Of carbon,	52,53
— oxygen,	41,78
— hydrogen,	5,69

And 100 parts of the second :

Of carbon,	51,45
— oxygen,	42,73
— hydrogen,	5,82

† From the experiments of Gay-Lussac and Thenard, it appears that olive oil contains, in 100 parts,

Carbon,	77,213
Oxygen,	9,427
Hydrogen,	13,360

100 parts of common resin contain

Carbon,	75,944
Oxygen,	13,337
Hydrogen,	10,719

Or of Carbon,

Oxygen and hydrogen in the proportions necessary to form water,	15,156
Hydrogen in excess,	8,900

According to the same chemists, 100 parts of copal consist of

Carbon,	76,811
Oxygen,	10,606
Hydrogen,	12,583

Or, Carbon,

Water or its elements,	12,052
Hydrogen,	11,137

100 parts of wax consist of

Carbon,	81,784
Oxygen,	5,544
Hydrogen,	12,672

Or otherwise, Carbon,	81,784
Oxygen and hydrogen in the proportions necessary to form water,	6,300
Hydrogen,	11,916

Chemistry. the preceding divisions, there are several other proximate principles of vegetables, the nature of which has not been sufficiently investigated, so as to enable us to class them according to their ultimate components; such as the narcotic principle of opium (*Annales de Chimie*, 1817), and the colouring matter.

Several different colouring principles have already been recognised, of which the principal are, 1. *Hemaline*, the colouring matter of logwood, soluble in alcohol and in water. 2. *Carthamine*, from the flowers of the *Carthamus tinctorius*, insoluble in water and alcohol, but soluble in alkalies. 3. *Indigo*, insoluble in its ordinary state in water, alcohol, and alkalies, but soluble in sulphuric acid. By the action of certain substances which absorb oxygen, indigo becomes green, and, in that deoxygenized state, is soluble in alkalies. M. Chevreul obtained from 100 parts of indigo of Guatemala the following results: (*Annales de Chimie*, Tom. 76. p. 29.)

Dissolved by water,	{ Green matter united to ammonia, a little deoxygenized indigo, gum and extractive,	12
Dissolved by alcohol,	{ Green matter, red resin, and a little indigo,	30
	{ Red resin,	6
Dissolved by muriatic acid,	{ Carbonate of lime,	2
	{ Red oxide of iron,	2
	{ Alumine,	2
Residue,	{ Silica,	3
	{ Pure indigo,	45
		100

When indigo is heated, it sublimes in the form of a violet-coloured vapour, much resembling iodine, and condenses in crystals upon the cooler part of the vessels.

Phenomena and Products of Fermentation.

Under the articles CHEMISTRY, BREWING, MALT-ING, and VINEGAR-MAKING, in the *Encyclopædia*, will be found the leading technical and theoretical observations upon the subject of fermentation. The result of this process is the conversion of a portion or the whole of the sugar contained in the original liquor into alcohol. Different wines contain different portions of alcohol, according to the circumstances under which they have been made, and the composition of the juice of the grape or other materials employed. To ascertain the quantity of alcohol which any wine contains, its acid may be saturated with potash; a given measure is then to be distilled with a gentle heat, nearly to dryness, and the deficient bulk of the distilled liquor is to be made up with distilled water. This mixture is to be shaken and set aside for twenty-four hours. Its specific gravity will then show the quantity of alcohol which the wine contains, and which may be immediately seen by reference to Mr Gölpin's tables, published in the *Phil. Trans.* for 1794. The following table, taken from Mr Brande's paper in the *Phil. Trans.* for 1811, shows the relative quantity of alcohol contained in the principal wines, &c.

WINE.	Proportion of Alcohol, per cent. by Measure.	WINE.	Proportion of Alcohol, per cent. by Measure.
Port	21.40	White Hermitage	17.43
Ditto	22.30	Red Hermitage	12.32
Ditto	23.39	Hock	14.37
Ditto	23.71	Ditto	8.88
Ditto	24.29	Vin de Grave	12.80
Ditto	25.83	Frontignac	12.79
Madeira	19.34	Coti Roti	12.32
Ditto	21.40	Rousillon	17.26
Ditto	23.93	Cape Madeira	18.11
Ditto	24.42	Cape Muschat	18.25
Sherry	13.25	Constantia	19.75
Ditto	18.79	Tent	13.30
Ditto	19.81	Sheraz	15.52
Ditto	19.83	Syracuse	15.28
Claret	12.91	Nice	14.63
Ditto	14.08	Lokay	9.88
Ditto	16.32	Raisin Wine	25.77
Calcevella	18.10	Grape Wine	18.11
Lisbon	18.94	Currant Wine	20.55
Malaga	17.26	Gooseberry Wine	11.84
Bucellas	18.49	Elder Wine	9.87
Red Madeira	18.40	Cyder	9.87
Malmsey Madeira	16.40	Perry	9.87
Marsala	25.87	Brown Stout	6.80
Ditto	17.26	Ale	8.88
Red Champagne	11.30	Brandy	53.39
White Champagne	12.80	Rum	53.68
Burgundy	14.53	Hollands	51.60
Ditto	11.93		

The most recent analysis of alcohol is by Mr Th. de Saussure (*Annales de Chimie*, t. 89), from whose researches it appears, that 100 parts, specific gravity 792, consist of

Carbon,	51.98
Oxygen,	34.32
Hydrogen,	13.70

100

It is probable that pure alcohol, free from water, consists of

100 parts elements of olefiant gas.
50 ————— of water.

Ethers are formed by the action of certain acids upon alcohol. The distillation of equal weights of sulphuric acid and alcohol produces *sulphuric ether*, of which 100 parts, specific gravity 0.7155 at 68°, contain

Carbon,	67.98
Oxygen,	17.62
Hydrogen,	14.40

100

Or deprived of adherent water, it may be considered as containing

100 parts elements of olefiant gas.
25 ————— of water.

Chemistry. So that the action of the sulphuric acid in converting alcohol into ether, consists in the removal of one-half of the elements of water which it contains, the proportion of the elements of olefiant gas remaining the same. If the whole of the elements of water be removed from alcohol, olefiant gas is the only result.

Nitric Ether is formed by gradually adding half a pound of nitric acid to two pints of alcohol contained in a glass retort. A pint and a half is to be distilled over by a very gentle heat, which, by redistillation with pure potash, affords nearly a pint of nitric ether. It is heavier than alcohol, and of a peculiar acrid flavour and fragrant. Passed through a red-hot tube it affords water, prussic acid, ammonia, oil, charcoal, carbonic acid and oxide, carburetted hydrogen and nitrogen, and its oxides.

When equal parts of nitric acid and alcohol are mixed, a violent action soon ensues, and a copious evolution of *nitrous etherised gas* is the result.

If 100 parts of mercury, dissolved in a measured ounce and a half of nitric acid, be added to two measured ounces of alcohol, and a gentle heat applied, a violent action ensues, during which a whitish powder, which is fulminating mercury, is deposited. It was discovered by Mr Howard, according to whom it consists of oxalate of mercury combined with nitrous etherised gas. Berthollet considers it as containing ammonia, oxide of mercury, and a peculiar vegetable body.

Hydriodic Ether has been obtained by M. Gay-Lussac by distilling a mixture of alcohol and hydriodic acid. (*Vide Annales de Chimie*, t. 91.)

For an account of the remaining Ethers, and some other vegetable products not noticed here, the reader is referred to the article CHEMISTRY in the *Encyclopædia*.

PART V.

ANIMAL CHEMISTRY.

The decomposition of animal substances is in general attended by more complicated results than those of vegetables. Ammonia is produced in abundance by the greater number of them, and certain combinations of sulphur and phosphorus with the compounds of carbon, &c. as afforded by vegetable decomposition. Oxygen, hydrogen, carbon, nitrogen, sulphur, and phosphorus, may be considered as the most frequently occurring ultimate elements of animal substances, and these give rise to various compounds produced by their destructive distillation, such as water, subcarbonate of ammonia, prussic acid, &c. &c. Animal substances are decomposed with peculiar phenomena by the acids. Sulphuric acid carbonizes them, and produces water, ammonia, and oily matter; and if heat be applied, the acid is decomposed, and sulphurous gas disengaged. The action of nitric acid is attended by yet more complicated results; it gives rise to the formation of water, carbonic acid, nitrogen, nitrous oxide, nitrous, prussic, acetic, malic, and oxalic acids, ammonia, and a peculiar yellow detonating compound.

Heated with liquid fixed alkalies, animal substances afford ammonia, carbonic and acetic acids, and a peculiar body which forms a soapy compound; and in general, when ignited with potash or soda, cyanurets

are formed, which, by the action of water, produce *hydrocyanates* (*prussiates*). **Chemistry.**

The proximate principles of animals have not yet been sufficiently investigated to enable us to arrange them according to their composition; they will be most conveniently examined as resulting from the chemical examination of the different products of animal bodies; these may be considered in the following order:

1. Blood.
2. Bile.
3. Milk.
4. Lymph.
5. Urine.
6. Cutis or skin.
7. Muscles, membranes, ligaments, horn, hair, &c.
8. Oil and fat.
9. Brain and nerves.
10. Shell and bone.
11. Concretions.

Blood.

This fluid, in the large arterial vessels of the more perfect animals, is florid red, and of a brownish red in the veins. Its specific gravity varies from 1083 to 1126. Its temperature is between 97° and 102°. When drawn from the circulating vessels, it undergoes a spontaneous change—forming a firm *coagulum* and a fluid *serum*. During this coagulation, there appears to be no increase of the temperature of the blood. (See Dr Davy's *Experiments. Journal of Science and Arts*, Vol. II. p. 247.)

Serum is a yellow fluid, of a specific gravity of 1029. At a temperature of 160° it coagulates into a firm whitish mass. Serum is also coagulated by alcohol, by most of the acids, and by the negative surface of the Voltaic pile. The substance in the serum which thus coagulates is called *Albumen*, a frequently occurring proximate principle of animals, and which exists in considerable purity in the white of egg.

Liquid Albumen is always slightly alkaline; it is soluble in water, and the solution furnishes a flocculent precipitate with corrosive sublimate, and muriate of tin; if not very dilute, it is also precipitated by the other coagulants of albumen. It soon putrefies at the temperature of 60°, and sulphuretted hydrogen is evolved. If dried by a heat between 100° and 120°, it forms a brittle transparent substance like amber.

Coagulated Albumen is insoluble in water; it does not putrify, but, exposed to dry warm air, it gradually becomes tough and semitransparent, and much resembles horn. When digested in water, it affords a weak alkaline solution of albumen. Submitted to destructive distillation, it affords products marked by abundance of ammonia, and a coal remains, very difficult of incineration. (See Mr Hatchett's Papers in the *Phil. Trans.* for 1799 and 1800.) Dr Marcet obtained the following results from the analysis of 1000 parts of the serum of human blood. (See *Medico-Chirurgical Trans.* Vol. II.)

Water,	900,00
Albumen,	86,80
Muriate of potash and soda,	6,60
Muco-extractive matter,	4,00
Subcarbonate of soda,	1,67

Chemistry.

Sulphate of potash,	0,35
Earthy phosphates,	0,60

1000

When serum or white of egg is coagulated by heat, there oozes from it a yellow fluid, which has been called *serosity*, and which consists of albumen, soda, and water. By washing the coagulum, almost the whole of the alkali may be separated; the acids, alcohol, and negatively electrified surfaces, also separate soda when they coagulate albumen. It appears; then, liquid albumen is a compound of soda and albumen with water; but that, after coagulation, the soda is found with the water, and the albumen solid and with scarcely any alkali.

The *Coagulum* or *Crassamentum* of Blood may be separated into two portions by copious washings with water; namely, into a white tough substance having all the essential characters of coagulated albumen, and which has been called *fibrine*, and into colouring matter.

The colouring matter diffused through the serum appears as a number of red globules, which in water part with their colour, and become white, and nearly transparent. In this state they appear to consist of albumen. The red substance is soluble in water, in muriatic, dilute sulphuric, acetic, tartaric, oxalic, and citric acids; the solutions are red by reflection, and green by transmitted light. Alkalies also form red solutions of the colouring principle. Nitric acid instantly destroys it.

Hence it appears that the blood consists of water, albumen, colouring matter, subcarbonate of soda, and certain saline substances, of which common salt is the principal. The cause of its spontaneous coagulation is unknown; the effect which we observe is the solidification of one part of the albumen with the colouring globules, forming the *crassamentum*; while another portion of the albumen remains fluid, constituting the *serum*.

Bile

Is a bitter greenish-yellow viscid fluid, secreted from venous blood in the liver; its specific gravity fluctuates between 1020 to 1030. The bile of the ox has been principally examined. It is alkaline. It soon putrefies, exhaling an insupportable stench. It dissolves in water, and is only imperfectly coagulated by alcohol, and by acids.

According to the analysis of Thenard (*Traité de Chimie*, p. 556, Vol. III.) bile consists of

Water,	-	-	700
Resinous matter,	-	-	15
Picromel,	-	-	69
Yellow matter,	-	-	4
Soda,	-	-	4
Phosphate of soda,	-	-	2
Muriates of soda and potash,	-	-	3,5
Sulphate of soda,	-	-	0,8
Phosphate of lime and magnesia,	-	-	1,2
Traces of oxide of iron,	-	-	

Picromel is a principle peculiar to bile, of an acrid bitter and sweet taste, viscid consistency, and which forms a peculiar triple compound with the resin and soda. It is the substance which gives bile its leading characters. It may be obtained by adding to bile an excess of acetate of lead; it is then filtered, and subacetate of lead is added to the filtered liquor, a flocculent precipitate is formed, which is to be washed, and dissolved in distilled vinegar; a current of sulphuretted hydrogen passed through this solution separates the lead; the vinegar is then driven off by heat, and picromel remains.

The yellow matter is also peculiar to bile, and seems to render it easily putrescible.

Milk.

The gastric secretion of animals coagulates milk, and the cream having been separated, converts it into *curd* and *whey*.*

The *curd* or *caseous part* of milk (of the cow) is to be considered as a modification of albumen. The *whey*, by evaporation, affords *sugar of milk*, a white crystallizable substance, of a sweet taste, composed, according to Guy-Lussac and Thenard, of

Carbon,	38,825
Oxygen,	53,834
Hydrogen,	7,341

or of

Carbon,	-	38,825
Oxygen and hydrogen in the proportions of water,	-	61,175

Butter, according to Braconnot, consists of 60 parts of yellow oil remaining fluid at low temperatures, and 40 parts of concrete oil.

Lymph.

This fluid, which lubricates the various cavities of the body, and which may be collected in considerable quantities, by puncturing the lymphatic vessels in large animals, has the properties of a weak solution of albumen; it contains the same salts as the serum of blood. The liquor of dropsies is also analogous in composition, but the proportion of albumen varies according to the circumstances under which it has been thrown out. In a case of hydrocele, which had been a long time forming, the liquor afforded a very small proportion (about 3 per cent.) of albumen. The sac filled in five days after the operation, and the fluid then contained 12 per cent. of albumen, and was readily coagulable by the usual means.

Urine.

This secretion is constantly varying in composition. It is when healthy always acid, but in cases of injury done to the nerves of the kidneys, it is alkaline. The following are the substances contained in human urine.

Water,	} Uncombined, and giving acidity to the urine.
Carbonic acid,	
Uric acid,	
Phosphoric acid,	

* See Sir Everard Home on the *Coagulating Power of the Secretion of the Gastric Glands*, *Phil. Trans.* 1813. p. 96.

Chemistry.

Muriate of soda.
 Phosphate of soda.
 Phosphate of ammonia and magnesia.
 Phosphate of lime.
 Muriate of ammonia.
 Sulphates of potash and soda.
 Urea.
 Albumen. } Occasional ingredients.
 Gelly. }

Uric acid is occasionally deposited by urine in small red crystals; these are soluble in caustic alkalies, and the uric acid is precipitated from such solutions by muriatic acid. Boiling water dissolves about $\frac{1}{100}$ of its weight of this acid. It is readily soluble in warm nitric acid, and the solution yields by evaporation a *rose red compound*, very characteristic of this acid.

Urea is the principle which gives to urine its leading peculiarity, that of affording abundance of ammonia during its putrefaction or decomposition by heat. It may be obtained by evaporating urine, voided about six hours after a meal, to the consistence of syrup; to which is to be added four times its weight of alcohol, and a gentle heat applied; the alcoholic solution, by evaporation in a water-bath, affords a crystalline residue of urea. This substance has an acrid taste, and urinous smell; it is soluble in water and alcohol; it forms with nitric acid a compound having the appearance of pearly scales. By heat, it affords two-thirds its weight of subcarbonate of ammonia, and a considerable portion of benzoic acid. Ammonia and acetic acid are the products of the decomposition of its aqueous solution: hence the production of various ammoniacal salts in putrid urine. Alkalies decompose urea, and exhale ammonia. It consists, according to Vauquelin and Fourcroy, of

Nitrogen,	-	32,5
Oxygen,	-	28,5
Carbon,	-	14,7
Hydrogen,	-	11,8

Culis.

The *cutis*, or *true skin* of animals, consists principally of gelatine, a substance soluble in water, and forming a solution, which, if concentrated while hot, gelatinises on cooling. The solution affords a copious precipitate with vegetable astringents, and with nitrate of mercury it deposits white flocculi with solution of chlorine. Gelatine is soluble both in acids and alkalies. It is insoluble in alcohol, which precipitates it from its aqueous solution. Isinglass, size, and glue, are varieties of gelatine. It contains, according to Thenard and Gay-Lussac,

Carbon,	-	47,881
Oxygen,	-	27,207
Hydrogen,	-	7,314
Nitrogen,	-	16,998

When submitted to destructive distillation, it affords

the usual products of animal bodies. When dry, it suffers no change by exposure to air, but its solution very soon putrefies.*

Muscular Flesh, &c.

When the *muscular parts* of animals are washed repeatedly in cold water, the fibrous matter which remains consists chiefly of albumen, and is in its chemical properties analogous to the clot of blood. Muscles also yield a portion of gelatine, and the flesh of beef, and some other parts of animals, afford a peculiar substance of an aromatic flavour, called by Thenard *osmazome*. *Ligaments, horn, nail, feathers*, and the *cuticle*, consist principally of albumen. *Elastic ligament and tendon* yield a portion of gelly. The *membranes* consist principally of gelatine.

Hair consists principally of a substance, having the properties of coagulated albumen. It also contains gelatine, and the soft kinds of hair yield it more readily than those which are harsh, strong, and elastic.

Vauquelin discovered in hair two kinds of oil; the one white, and existing in all hair, the other coloured, yellow from red hair, and dark coloured when obtained from dark hair. Black hair also contains iron and sulphur. He supposes that where hair has become suddenly grey, the effect is produced by the evolution of acid matter, which has destroyed the colour of the oil.

Oil and Fat.

These proximate principles contain no nitrogen. They are compounds of carbon, hydrogen, and oxygen, in which the two former elements abound. These bodies have lately been laboriously investigated by MM. Chevreul and Braconnot (*Annales de Chimie*, Tom. 88, 93, 94, and 95). The different kinds of fat are separable into two substances, one of which fuses at about 50°, the other at 105°. They may be separated from hogs-lard, for instance, by boiling in seven or eight times its weight of alcohol; the liquor is decanted, and fresh alcohol added, till the whole is dissolved. Each portion of alcohol deposits, on cooling, crystals of the least fusible substance; the other is obtained in the form of oil, by evaporating the mixed alcoholic solutions to one-eighth their original bulk. The reunion of these two principles produces the original fat. By exposing oils solidified by cold to pressure, they too afford a fluid and solid matter. The following are the relative proportions of oil and fat afforded by several of these substances:

	Oil.	Fat.
Butter made in summer,	60	40
Ditto made in winter,	37	63
Hogs-lard,	62	38
Beef marrow,	24	76
Mutton ditto,	74	26
Goose fat,	68	32
Duck's fat,	72	28

* Mr Hatchett's admirable Dissertations in the *Phil. Trans.* 1800 and 1799, contain a great body of information in this department of animal chemistry. The reader is also referred to Dr Bostock's papers in *Nicholson's Journal*, Vol. XI. and XIV.

Chemistry.

	Oil.	Fat.
Turkey's fat, - - -	74	26
Olive oil, - - -	72	28
Almond oil, - - -	76	24

The fat is fusible at different temperatures, and the fluid part of olive and almond oil requires a very low temperature for its solidification; so that it may perhaps prove very useful for watches and clocks. Chevreul calls the oily part *elaine*, from *ελαιον*, oil, and the fat substance he terms *stearine*, from *στέαρ*, suet.

When fat is acted upon by alcalics, it suffers a change by which it affords a peculiar substance of a pearly lustre, called by Chevreul *margarine*, and an oily matter. A sweet substance, a volatile, and an orange-coloured substance, are also produced. Margarine has acid properties, and exists in soap, as *margarate of potash*.

Brain and Nerves.

According to Vauquelin, the cerebral substance consists of

Water, - - -	80,00
White fatty matter, - - -	4,53
Red fatty matter, - - -	0,70
Albumen, - - -	7,00
Osmazome, - - -	1,12
Phosphorus, - - -	1,50
Acids, salts, and sulphur, - - -	5,15

100

The pulp of nerves seems to be of a similar nature.

Shell and Bone.

These may be considered as containing an animal substance or hardening matter. The animal substance is in porcellaneous shells, and in the enamel of teeth, is gelatine; in mother of pearl shell, and in bone, it is a compound of gelatine and albumen; and, consequently, the former are entirely dissolved by dilute muriatic acid, while the latter leave a cartilaginous skeleton. The hardening principle of shell is generally carbonate of lime; in some *crustacea* and *zoophytes* it is a mixture of carbonate and phosphate of lime; and in bone it consists of phosphate of lime, with a relatively small proportion of carbonate. (See Mr Hatchett's Papers, *Phil. Trans.* 1799 and 1800.)

Concretions.

Concretions occur in various parts of the animal body; they are often of the same composition as bone, as in the case of ossifications and exostoses.

Concretions of the gall-bladder, and biliary ducts, consist chiefly of a peculiar substance called *adipocire*, or *cholesterine*, combined with from 6 to 12 per cent. of the colouring matter of bile. Picromel, which is not found in healthy human bile, occasionally occurs in human biliary calculi. Gallstones sometimes contain a large quantity of the resin of bile, and sometimes appear to consist entirely of inspissated or thickened bile.

VOL. III. PART I.

Urinary calculi vary considerably in their composition. The substances hitherto discovered in them are as follow:

Uric acid.

Phosphat of lime.

Ammoniac-magnesian phosphate.

Oxalate of lime.

Cystic oxide.

These substances are generally more or less mixed in urinary calculi, and their different kinds may therefore be arranged as follow:

1. *Uric calculus*.

2. *Bone earth calculus*, consisting chiefly of phosphat of lime.

3. *Ammoniac-magnesian*, or *triple phosphate*.

4. *Fusible calculus*, consisting of a mixture of the two last.

5. *Mulberry calculus*, or oxalate of lime.

6. *Cystic calculus*, consisting of a peculiar substance, which Dr Wollaston has called *cystic oxide*. (See *Phil. Trans.* 1810.)

The properties of the four first calculi will be obvious from the preceding matter of this article. The calculus composed of oxalate of lime, when in the bladder, has much resemblance to a mulberry; when formed in the kidney, it often looks like a hemp-seed. Before the blow-pipe it affords quicklime. The cystic oxide is dissolved by muriatic, nitric, sulphuric, phosphoric, and oxalic acids; by potash, soda, ammonia, lime-water, and carbonates of soda and potash. Its combinations with the acids crystallize in slender needles; those with the alcalics in small grains. It is nearly insoluble in water, alcohol, acetic, tartaric, and citric acids, and in carbonate of ammonia.

The above substances, excepting cystic oxide, are often in alternate layers in calculi, and two or more are sometimes mixed so as not to be separable except by analysis. Urinary calculi have been found in the horse, composed of phosphate and carbonate of lime; in the ox, of carbonate of lime; in the dog, of a mixture of phosphate of lime and triple phosphate; in the hog, of carbonate of lime; in the rabbit, of phosphate and carbonate of lime. In the excrements of the Boa constrictor, and of some birds, uric acid is found. Independent of hair balls, calculi are sometimes found in the intestines of animals, composed of triple phosphate and phosphate of lime.

Gouty concretions consist of urate of soda.

Upon the subject of urinary calculi, the reader is referred to Dr Wollaston's Dissertations in the *Philos. Trans.* 1797—1810; to Mr Brande's papers in the same work; and to an *Essay on the Chemical History and Medical Treatment of Calculous Disorders*, by Alexander Marcet, M. D.

Animal Functions.

Under this head, the processes concerned in the productions of animal substances are considered in the article CHEMISTRY in the body of the work. These processes may be considered under the heads *Digestion*, *Transpiration*, *Respiration*, and *Secretion*.

The food, masticated in the mouth, is mixed with

Chemistry
||
Chénier.

saliva, a fluid containing saline matter and albumen, and thus propelled into the stomach, where it becomes converted into a peculiar pulpy mass called *chyme*. This change appears principally dependent upon the *gastric juice*, which, by analysis, does not greatly differ from saliva, and yet produces very different effects. The nature of its action is not known. In the small intestines, the chyme is mixed with bile and pancreatic secretion; and hence *chyle* is formed, which, absorbed by the lacteals, and mixed with lymph, is carried into the venous system. Human chyle has not been examined: from the dog and cat it is a white fluid, of a slightly sweet taste, and coagulates soon after removal from its vessels. Its principal component part is albumen; and sometimes the serous part of chyle contains a body analogous to sugar of milk. The chyle of graminivorous animals is more transparent than the former, and nearly colourless; it coagulates spontaneously, and the coagulum is albuminous.

The matter which is transpired by the surface of the body consists of water, carbonic acid, acetic acid, phosphoric acid, muriate of soda, and a peculiar odorous animal matter. By the process of respiration, the blood is exposed to the action of air in the lungs. Having circulated throughout the body, it enters by the *venæ cavæ* with the contents of the thoracic duct, into the right auricle of the heart; thence into the right ventricle, whence it is propelled through the lungs, and returns in the state of arterial blood to the left cavities of the heart, and is circulated as before. In the air expired, there is a deficiency of oxygen; instead of containing 21 *per cent.*, it only affords 18 or 19; and there is a proportion of carbo-

nic acid formed, exactly equivalent in volume to this deficiency. Aqueous vapour is also exhaled with the expired air. It appears, then, that the great end answered by respiration is the removal of carbon from the blood; it thus passes from the state of venous to arterial; it becomes fit for the nourishment, and reproduction of parts, and for the formation of secretions; and, while the parts of the body are continually removing by the absorbents, and the materials carried into the blood by the lymphatics, so they are constantly reproducing by the arteries, under the influence of the nervous system. It is probable that the colouring matter of blood remains always the same, and that in venous blood it is obscured by carbon, which, when removed by the air, exposes its brilliant tint, as seen in arterial blood, or in venous blood which has been exposed to oxygen. The nervous system seems to preside over secretion; for, when the nerves going to any gland are injured or divided, the secretion is modified either in quantity or quality; and, if it were possible to remove the nervous ramifications altogether, probably no secretion would take place. Animal heat is also the effect of the joint agency of the circulating and nervous system; for, when the great centre of nervous energy, the brain, is removed, there is no production of heat, though, under such circumstances, circulation may be kept up by artificially continued respiration, for a considerable period. Upon these subjects, however, which are rather physiological than chemical, we refer our readers to the researches of Sir E. Home (*Phil. Trans* 1814), and to Mr Brodie's papers in the *Philos. Trans.* for the year 1811.

(M. M.)

Chemistry
||
Chénier.

CHÉNIER (MARIE JOSEPH DE) was the son of Louis Chénier, well known as the author of *Recherches Historiques sur les Maures*, and *Revolutions de l'Empire Ottoman*. He was born in 1764, at Constantinople, where his father at that time acted as Consul General from France. At a very early period of life he entered into the French army, but he soon relinquished the military profession, and settled at Paris, where he devoted much of his time to literary pursuits. He commenced his dramatic career by a tragedy, which was acted in 1786, and was completely unsuccessful. A few years afterwards, availing himself of the political feelings of the period, he produced the tragedy of Charles IX., which was received with vast applause by the party which predominated at the time. This was followed by *La Mort de Calas*, and the republican tragedies of *Gracchus* and *Timoleon*. These dramas, in a great measure, owed their popularity to existing circumstances, and the author's talent of addressing himself to the prevailing feelings of the multitude. His performances, however, were instrumental in procuring him a seat in the National Convention, and obtained him the highest theatrical reputation, till he unfortunately brought forward a tragedy founded on the accession of Cyrus to the throne of the Medes, a subject which, as it gave less scope to

political allusion than his former productions, and had been previously treated with greater ability by other writers, failed more completely even than the piece with which he first laid claim to the favour of the public. After this failure Chénier appears to have distrusted his dramatic genius, and chiefly employed himself in translating or imitating the most celebrated productions of the Greek and German stage.

Chénier, however, did not confine himself to dramatic compositions, but cultivated almost every species of poetry with tolerable success. His productions are chiefly satirical, lyric, and political. Being engaged in a variety of literary as well as political quarrels, and being naturally of a haughty irritable temper, he was naturally led to employ his talents for poetry and satire on all who had provoked his enmity. His works of this description, accordingly, are often misapplied, but are distinguished by considerable gaiety and energy of composition. His lyric productions, of which he published a collection in 1797, consist partly of odes imitated from the *Poems of Ossian*. Most of his other poems, as his *Poème sur l'Assemblée des Notables* and *Dithyrambe sur l'Assemblée Nationale*, allude entirely, as their name imports, to the political events of the day.

Chenier
||
Cheshire.

Chenier also distinguished himself as a prose writer by his productions in the *Mercur de France*, and the discourses which he prepared for the different academies of which he was a member, which chiefly turn on subjects connected with the progress of knowledge in Europe, and the literary history of his own country. In consequence of a task assigned by Bonaparte to the Institute, of which Chenier was a member, he undertook to give a historical and critical account of the most celebrated productions, both in prose and verse, which had enriched French literature from the year 1788 to 1808. This sketch was originally read at one of the sittings of the Institute, and was afterwards published under the title *Tableau Historique de l'état et des progrès de la Littérature Française depuis 1789*. This work comprehends a notice of all the best works which had appeared during that period, from the light class of romances to the most important treatises on morals, politics, and legislation; and in poetry it embraces a review from the highest epic to burlesque and mock heroic.

Many of the orations and discourses pronounced by Chenier in the different political assemblies which were formed during the existence of the French republic, and of almost all which he was a member, related to similar topics—proposals for legislative measures with regard to literary works—the encouragement of arts and systems of public instruction. Those orations, which were truly political, breathed all the violent spirit of the time and of the assemblies in which they were delivered. As he took an active part in the distracted politics of his country, and was engaged, on one side or other, in most of the revolutions by which she was at that time agitated, his character was frequently the object of the blackest calumnies, his property of confiscation, and his person of proscription. All this was little favourable to literary improvement. But, when France at length settled under the absolute dominion of one ruler, by being precluded from political intrigue and discussion, he had ample leisure left for study and composition. He continued thus usefully employed, in a state of comparative tranquillity, till his death, which happened at Paris, on the 10th January 1811.

The character and writings of Chenier partook strongly of the spirit of the times in which he lived. The former was marked by turbulence, restlessness, and ambition; and although some of his poems, as well as his more recent prose compositions, show that his taste was not naturally that of the school of the French Revolution, yet many of his tragedies and literary discourses are disfigured by that exaggeration of sentiments and ideas, as well as that declamatory and inflated style, which the tone and feelings of the period had introduced or propagated. (M.)

Boundaries.

CHESHIRE is divided from Lancashire by the rivers Mersey and Tame; from Derbyshire and Staffordshire by the rivers Goyt and Dane, and a range of hills; and in a great measure from Flintshire and Denbighshire by the river Dee and its estuary, a small portion of the hundred of Broxton lying to the west of this general boundary. The form of this county is singular, being distinguished by two points, projecting, the one into the Irish Sea, between the

Mersey and the Dee, which constitutes the hundred of Wirral; and the other running up towards Yorkshire, between Lancashire and Derbyshire, forming the extremity of the Macclosfield hundred. If these points were cut off, the figure of Cheshire would approach nearly to that of an oval. The greatest breadth of this county, from north to south, is about 30 miles; its greatest length, from the extremity of the hundred of Wirral, at Kiddington Green, to Britland Edge, on the borders of Yorkshire, is 58 miles; across the middle part of the county, however, the length is not 40 miles. The projection between the Dee and Mersey is about 20 miles long and 6 broad; and that towards Yorkshire about 15 miles long, and seldom above 3 miles broad.

Cheshire contains one city, which is also the county town, Chester; seven hundreds; thirteen market towns, including Chester; namely Stockport, Knutsford, Altringham, Congleton, Frodsham, Macclesfield, Malpas, Middlewich, Nantwich, Neston, Northwich, Sandbach, and Tarporley; and eighty-six parishes. As, however, many of these parishes are of great extent, and comprise numerous townships, and more than one chapelry having the privilege of baptism and sepulture, the number of parishes and places assessed to the poor's-rates, and other county and parochial rates, amounts, according to the last returns, to 491. This county is in the province of Canterbury, and diocese of Chester; within this diocese are comprehended Cheshire, Lancashire, and part of Yorkshire, Denbighshire, Flintshire, Westmoreland, and Cumberland. It is a county palatine, and is not included in any of the circuits, having a chief-justice of its own.

The area of Cheshire comprises about 1200 square miles, or 676,600 acres, of which a much larger proportion is in cultivation than in most other English counties; there being only 28,600 acres of waste land, commons, and woods; 18,000 in peat bogs and mosses; and 10,000 in sea sands, between the estuaries of the Dee and Mersey; the remainder, 620,000 acres, is in cultivation. The general character of the surface is flatness; the principal hills are on the borders of Derbyshire, which are connected with those of that county and Staffordshire; and stretch along the eastern side of the parishes of Astbury, Prestbury, and Motbram, about 25 miles. Near Frodsham, there is a bold promontory, overlooking the Mersey, which is the first of an interrupted ridge of hills that crosses the county from north to south, on its western side, as far as Malpas; this high ground, after crossing the elevated district of Delamere forest, appears again in the insulated rock of Beeston, which is nearly 386 feet in height. The last link on this chain of hills are those of Broxton. The ground near Macclesfield is also elevated. With these exceptions, and that of a low chain of hills stretching from north to south through the hundred of Wirral, Cheshire is more uniformly flat than any other county in this part of England.

There is not much variety of soil; sand and clay, with one or the other predominating in various proportions, constitute the soil of nearly the whole of Cheshire: that part of the county which stretches towards Yorkshire consists principally of peat moss;

Cheshire.

Extent.

Divisions.

Surface.

Soil.

Cheshire. a soil which also prevails to a less considerable extent near Coppenhall and Warmincham, and in some parts of the forest of Delamere; the greater part of the forest, however, consists of sterile white sand or gravel. The most prevalent subsoils are marl, clay, and redgrit rock, or sandstone.

Timber. Cheshire, viewed from a height, appears covered with wood; but this appearance arises from the smallness of the enclosures, and the great number of large trees in the hedge-rows; otherwise it is not a well-wooded county. Its forests, which formerly were extensive, consisted of those of Delamere, Macclesfield, and Wirral; the first contained 10,000 acres, 2000 of which have been enclosed. The quantity of timber in the hedge-rows and coppices exceeds the general average of the kingdom; the best as well as the most common is oak. In Dunham Park, near Altringham, the seat of the Earl of Warrington, there are some remarkably large old oaks. Alderley Park is equally celebrated for its beech trees.

River. The principal rivers are the Dee, the Weaver, the Dane, and the Tame; the Mersey, though frequently described as a Cheshire river, seems to us more properly to belong to Lancashire. The Dee, which rises in Wales, enters this county near Aldford; from Bangor Bridge it is navigable for barges; at Chester Bridge it meets the tide; at Chester a ledge of rocks runs across the bed of the river; from this place to the sea, its natural course forms a broad sandy estuary; but an artificial channel has been formed at great expence, on the south side of the river, nearly half way to the sea, which is navigable for ships of 600 tons burden. It falls into the Irish Sea, about fourteen miles north-west of Chester. At the time when the artificial channel was made, much land was gained from the tide by embankments, and much has been subsequently recovered. The Weaver rises in Cheshire on Bulkley Heath, and flows entirely through the county, till it joins the Mersey at Wyton; from Frodsham Bridge to Winsford Bridge, a distance of 20 miles, it is rendered navigable by means of locks and weirs; the fall is 45 feet 10 inches, and there are 10 locks; the course of this river is about 33 miles. The Dane rises in Macclesfield forest; during the first part of its course, it divides Staffordshire and Cheshire; at Congleton it enters the latter, and falls into the Weaver at Northwich; its course is about 22 miles. The character of these rivers differs much. The Weaver is narrow, deep, and slow; the Dane is broad, shallow, and swift. The Tame rises in Yorkshire; during the greater part of its course, which is only ten miles, it forms the boundary between Cheshire and Lancashire, and falls into the Mersey near Stockport.

Canals. Cheshire is intersected by the Duke of Bridgewater's canal; the Grand Trunk; the Ellesmere; the Chester and Nantwich, and the Peake Forest. The first runs through about twenty miles of the county, entering it to the east of Ashton, and joining the Mersey at Runcorn. The Grand Trunk canal communicates with the Duke of Bridgewater's at Preston-Brook, and passing by Northwich and Middlewich, enters Staffordshire near Lawton. There

are four tunnels in the course of this canal through Cheshire, one of which, near Preston-on-the-Hill, is 1241 yards in length, 17 feet 4 inches in height, and 13 feet 6 inches in width. The Ellesmere canal joins the Mersey at Whitby, and after passing the east end of the Hundred of Wirral, and the south-east of Broxton, it connects with the Dee and the Chester canal at Chester: another branch forms a junction with the Chester canal at Hurleston. The Chester canal begins at the Dee, on the north of Chester, and passing through Christleton, Warrington, Hargrave, and to the north of Beeston Castle, terminates at Nantwich. The Peake Forest canal joins the Ashton and Oldham canal at Ashton-under-Line; it crosses the Tame near Duckinfield, and passing through Hyde, Marple, and Disley, enters Derbyshire near Whaley Bridge. Near Marple it is carried over the Mersey by an aqueduct of three arches and 100 feet in height. In the northern parts of Cheshire there are several small lakes called *Merres*.

The mineral productions of this county are coal, copper, lead, cobalt, and rock-salt. Coal abounds in the north-eastern parts, in a district of about ten miles from north to south; there are also some coaleries in the Hundred of Wirral, one of which extends $1\frac{1}{2}$ mile from high water-mark under the river Dee. Copper, lead, and cobalt, are found at Alderby Edge, and copper in the Peckforton Hills; but none of these ores are by any means abundant.

As the rock-salt and the brine-springs of Cheshire are naturally connected, and are found in the same districts, we shall consider them together. The brine-springs are principally met with in the valley through which the Weaver and the Wheelock flow; those from which salt is at present manufactured are at Lawton, Wheelock, Roughwood, in the townships of Anderton, Bechton, Lettwich, Middlewich, and in the neighbourhood of Northwich and Winsford. The brine-springs at Wheelock are at the depth of 60 yards. The brine is rich, but varies in strength; the strongest brine-springs are those of Anderton; those at Lettwich are the weakest.

The brine-springs of Cheshire were probably known to the ancient Britons. It is certain that salt made from them was one of the principal articles of the commerce of this county before the Norman Conquest. The discovery of the rock-salt, on the other hand, is very recent; not having been made till 1670, during a search for coal, near Northwich. Since that period it has been found abundantly in the townships of Witton, Wincham, and Marston. The rock-salt is met with at various depths below the surface, from 28 to 48 yards; some of the strata are only four feet thick, and others 40 yards. In the mines near Northwich there are only two beds of rock-salt; but in other parts three beds have been found. These beds are divided from one another by strata of indurated clay or hard flag-stone, in which there are frequently found pieces of rock-salt. The muriate of soda, in the great body of the rock-salt, is mixed with a considerable portion of clay, oxide of iron, and sulphate of lime. In the lower strata, the rock-salt is a purer muriate of soda. The rock-salt is extremely hard, and in many cases

Cheshire. requires to be blasted with gunpowder. The largest mine at present worked is that of Wilton; its depth is 330 feet, and its area nearly two acres; the ceiling, which is about 20 feet high, is supported by pillars 15 feet thick, each containing 294 solid yards of rock-salt. Fifty or sixty thousand tons of rock-salt are obtained annually from the pits in the neighbourhood of Northwich, which is the great seat of the salt trade in this county. One-third of the rock-salt is dissolved in water and crystallized by evaporation, and two-thirds are exported in its native state.

By the Report of the Committee of the House of Commons, on the use of rock-salt in the fisheries, printed May 1817, it appears, that the capital embarked in the salt trade of Lancashire and Cheshire is about L. 600,000; that on an average of five years to the 5th of April 1817, 240,000 tons of white salt had been made annually in these two counties; that from 300 to 330 flats and barges are employed in conveying the salt; that 267 people are employed in the salt mines; that 6500 are employed in the manufacture of salt; and that 400 tons of iron are consumed annually in this manufactory.

Quarries. Quarries of excellent freestone are found at Run-corn, Manley, and Great Behington; limestone only at Newbold Astbury; millstones at Mowcop Hill; and sandstone fit for glass near Macclesfield. Marl abounds in almost every part of the county.

Landed property is, in general, very little divided in this county; there being, according to Mr Holland, fifty noblemen and gentlemen who possess in it property of the annual value of from L. 3000 to L. 10,000 a-year; and at least as many others with estates of from L. 1000 to L. 3000 a-year.

Cheshire. With respect to agriculture, Cheshire is almost entirely a dairy county: its arable husbandry is neither extensive nor of superior character. The principal dairies are about Nantwich, and in the district between the Dane and the Weaver; they are found, however, in every part of the county where the soil consists of clay. The number of cows kept for the dairy is about 32,000; and the quantity of cheese annually made about 11,500 tons. The average quantity of cheese from each cow annually is estimated at 300 lb.; eight quarts of milk, the average daily quantity yielded by each cow, producing one pound of cheese. In Lyme Park there is a herd of cattle of the same wild breed as those at Chillingham in Northumberland.

Potatoes. The ground in the vicinity of Frodsham and Altringham produces abundant crops of excellent potatoes; in the latter parish, where sea-mud is used, 100,000 bushels are generally grown annually.

Manufactures. The cotton manufactures of Lancashire have extended into the contiguous parts of Cheshire, particularly at Stockport. Silk is manufactured at Macclesfield and Congleton, where there are large silk-mills; hats at Stockport; white and red lead at Chester; and gunpowder at Tholwall. Tanneries are very numerous, and on a large scale, in the middle and north of the county.

Poor-Rate. In 1803, the poor-rates amounted to L. 84,991. In 1813, 434 parishes and places paid the sum of L. 125,630. There were no returns from 57 places. In 1801, the number of inhabited houses was 34,482,

and of uninhabited 1139. The total number of inhabitants was 191,751. Of these, 92,759 were males, and 98,992 females: 38,823 were employed in agriculture, and 67,447 in trade, manufactures, and handicrafts. According to the returns in 1811, there were,

CHILI. Some account of this country will be found in the *Encyclopædia*, to which the reader is referred for various particulars relative to its early history and its trade. Boundaries and Extent.

Chili is situated on the western shore of South America, between the 24th and 45th degrees of south latitude. It is estimated to stretch along the shore 1260 miles; but its breadth varies as the great chain of the Cordilleras, which forms its eastern boundary, approaches the sea, or recedes from it. Between the 24th and 32d degrees of south latitude, the space between the mountains and the Pacific Ocean, which forms the breadth of Chili, is about 210 miles. From the 32d to the 37th it is only 120; and near the archipelago of Chiloe, at the broadest part of Chili, it extends to 300 miles in breadth. On these data, the superficial extent of Chili may be estimated at 378,000 square miles.

Chili is separated from Peru on the north, from the viceroyalty of Buenos Ayres on the east, and from the land of Magellan on the south, by the Cordilleras, which form an almost insurmountable barrier between it and the neighbouring countries. The roads which lead across these lofty ridges are impassable except in summer, and the path is frequently so narrow, that a horseman can with difficulty effect a passage through it.

Molina, in his valuable account of this country, describes it under three great natural divisions. The first comprehends the islands; the second, Chili properly so called; and the third includes the Andes, or that part of Chili which is occupied by these mountains. Divisions

1. The islands belonging to Chili are, the three Coquimbanes, Mugillon, Totoral, and Pajaro, which last is about six or eight miles in circumference, and wholly desert; the two islands of Juan Fernandez, known under the name of Isola di Terra, and Masafuera, the former 42 miles in circumference, and inhabited by the Spaniards, the latter, though described as bearing the most inviting aspect, still

Chili.

uninhabited; and the island of Mocha, about 60 miles in circumference, and at present uninhabited, besides several other islands of inferior size and importance. The archipelago of Chiloe comprehends 82 islands inhabited by the Spaniards. Chiloe, which is the largest of these, and gives name to the archipelago, is 150 miles in length, and its capital is Castro. All these islands are adjacent to the coast, with the exception of those of Juan Fernandez, which are distant the one 330, and the other 420 miles from the shore.

2. That part of Chili which lies between the Andes and the sea, is divided into two equal parts, namely, the maritime country, and the midland country. The former of these is intersected by three chains of mountains running parallel to the Andes, with numerous intervening valleys, watered by delightful streams. The midland country is flat, being diversified only by a few occasional eminences, which render its appearance extremely picturesque and pleasing.

3. The Chilian Andes consist of a number of mountains, which appear to be chained to each other.

They are of prodigious height, and are covered with perpetual snow. At the foot of this vast ridge, gentle eminences and pleasant valleys, surrounded with high hills, are dispersed; but the principal ridge rises in general, abrupt and steep, with frequent and frightful precipices. In these lofty mountains are formed many brooks and rivers, which, when they are swollen by the melted snows, quickly accumulate into formidable torrents, and roar and foam amid glens and precipices, until they break out and extend over the plains. The lower ranges of mountains are covered with forests, and the vales beneath abound in corn and fruit. That portion of the Chilian Cordilleras which lies between the 24th and 33d degree of latitude is wholly desert; but further to the south, as far as the 45th degree, the mountains are inhabited by a variety of Chilian tribes.

Chili is partly occupied by the Spaniards, and part- Spanish part ly by the Indians. The Spanish part of it is situated of Chili. between the 24th and 37th degrees of south latitude, and is divided into the following thirteen provinces:

NAME.		Length. Miles.	Breadth. Miles.	CAPITAL.	S. Lat.
Copiapó	extending from Andes to the sea	300	210	Copiapó	26° 50'
Coquimbo	ditto - - -	135.	210	Coquimbo	29° 54'

The territory belonging to the Indians is situated between the 36th and 41st degrees of S. Lat. and is inhabited by three different nations, namely, the Araucanians, the Cunches, and the Huilliches. Of the remarkable people called *Araucanians*, we have given a full account under that Article.

Chili is blessed with a fertile soil, and with a mild and temperate climate; the air is remarkably salubrious, and the inhabitants are liable to few contagious diseases. They are, on account of these favourable circumstances, extremely attached to their native country, and always reluctant to quit it. Although the climate is not liable to either extreme of heat or cold, the different seasons regularly succeed each other, and are sufficiently marked. The spring commences, as in all countries in the southern hemisphere, in September, the summer in December, the autumn in March, and the winter in June. From the beginning of spring until autumn the south and south-east winds generally prevail, and they always bring with them a clear sky, while the north and north-west winds as regularly occasion rain. On the eastern and western sides of that great mountainous barrier which bounds Chili on the east, the dry and rainy seasons occur at precisely opposite periods. In Chili, the winter is the

Soil and
Climate.

rainy season, while on the eastern side of the mountains, in the provinces of Tucuman and Cuyo, the atmosphere is then always clear, and the inhabitants enjoy the finest season. The north and northerly winds crossing the torrid zone before they arrive in Chili, come loaded with vapours, and they are invariably followed with heat and rain. In Chili the heat of these winds is moderated in their passage over the Andes; but in the countries to the east, they are remarkable for their sultry and unhealthy properties, and are, according to the account of Molina, more suffocating than the sirocco which blows from Africa, and is occasionally felt on the shores of the Mediterranean and in Italy. The southerly winds coming, on the contrary, from the polar regions, are cold and dry. They blow constantly towards the equator; and as they disperse the vapours and drive them to the Andes, it seldom rains in Chili while they continue to blow. But these clouds, thus driven by the south winds towards the Andes, uniting with those which come from the north, occasion very heavy rains in all the provinces to the east of the mountains. It seldom rains in the northern provinces of Chili; but in the southern provinces rain is more frequent; and near the sea dreadful storms occasionally arise. In the islands, also, the rains are very frequent even in summer.

Chili.

Chili. Thunder is scarcely ever heard even in summer in those parts of the country which are at a distance from the Andes. In the maritime provinces, snow is never seen. In those nearer the Andes, it falls once perhaps in the course of five years; but it seldom remains on the ground for a single day. In the month of August, also, a white frost is sometimes seen, accompanied by a slight degree of cold. But this coldness does not continue above two or three hours after sunrise; from which time the temperature of the atmosphere is like that of a fine day in spring. In the Andes, on the contrary, snow storms are frequent, and snow falls in such quantities from April to November, that the ground is covered with it during all that time to a great depth, so that the mountains are quite impassable for the greatest part of the year. Abundant dews fall throughout most parts of Chili, which in a great measure supply the want of rains; and fogs are common on the coast, although they are generally dissipated as the day advances.

Rivers. Chili is watered by about 123 rivers, which have their sources in the Andes, and 52 of which communicate with the sea. Of these the principal are the Maule, in the province of the same name; the Bío-bío, two miles in breadth; the Cautén; the Tóten; the Valdivia, in the country of Arauco; the Chaivín; the Río-buena, and the Sinfondo, which discharges itself into the archipelago of Chiloe. The two most remarkable lakes are the Laquen, which the Spaniards call Villa-rica, which is 72 miles in circumference, and the Nahuelguapi, which is 80 miles in circumference.

Volcanoes and Earthquakes. Owing to the great quantity of sulphureous, nitrous, and bituminous substances contained in its soil, Chili is subject to volcanic eruptions and earthquakes. Among the Chilean Andes there are fourteen volcanoes in a constant state of eruption, and a still greater number from which smoke is occasionally discharged. These, however, being in general situated nearly in the middle of that range of mountains, their destructive effects are confined within certain limits, and seldom extend to the plains. There are only two volcanoes in the whole of the country not included in the district of the Andes, the principal of which is the great volcano of Villarrica, near the lake of the same name. This volcano, the summit of which rises into the region of perpetual snow, is in a constant state of eruption, and may be seen at the distance of 150 miles. Earthquakes are common in Chili. The inhabitants calculate upon three or four annually. They are, however, in general, very slight, and little attention is paid to them. Within a period of 244 years, from the arrival of the Spaniards to the year 1782, only five violent shocks have been experienced; the first in the year 1520; the second in the year 1647; the third in 1657; the fourth in 1730, when the sea was impelled against the city of Concepción, and overthrew its walls; and the fifth in 1751, during which that city was completely overwhelmed by the ocean. At present the shocks are less violent than formerly, and are generally confined to horizontal or oscillatory motions. The inhabitants are also forewarned of these convulsions by the hollow noise which precedes them, and they have built

both their houses and their cities upon such a plan as to afford them an easy and safe retreat from the effects of this calamity. In the cities, the streets are so broad that the inhabitants are always safe in the middle of them, in whatever direction the houses may happen to fall; and all those which belong to the richer classes have spacious courts and gardens attached to them, which serve as a place of retreat in case of danger. These precautions are quite sufficient to prevent any useless alarms, more especially as the earthquakes which happen in this country have never been attended with any considerable sinking of the earth, or with the falling of buildings. It is supposed that the volcanoes in the Andes are so many outlets, which, by affording vents to the subterraneous fluid, render its action less violent, and its effects consequently less destructive.

The soil of Chili is remarkably productive, and the country, in its uncultivated parts, every where produces the most profuse and vigorous vegetation. The plains, the valleys, and the mountains, are covered with a variety of beautiful trees, many of which preserve their verdure throughout the whole year, and each season produces its peculiar succession of vegetables in the greatest perfection. Different travellers have given the most extraordinary accounts as to the fertility of the soil. In Frazier's *Voyage* it is mentioned, that it yields from sixty to eighty, and even a hundred fold. Others mention, that the crop is considered poor if it does not exceed the proportion of one hundred to one, while there are some who state the increase at three hundred to one. Molina mentions, that he has himself witnessed instances of lands producing one hundred and twenty, and even one hundred and sixty for one. These, however, he states to be extraordinary instances. The maritime districts are less fertile than the middle districts, and these again yield in point of fertility to the rich valleys of the Andes.

The common produce in the middle districts is stated by Molina to be from sixty to seventy for one, and in the maritime districts to be from forty to fifty. The soil of Chili is extremely favourable to the production of maize, wheat, barley, and rye. Hemp and flax also grow extremely well; but as the exportation of this produce was rigorously prohibited under the regime of the mother country, the inhabitants were accustomed to raise no more of these articles than what was sufficient for their own domestic consumption. In the northern provinces many of the tropical productions grow to great perfection. The principal of these are the sugar-cane, the cotton plant, the banana, the pine apple, the sweet potatoe, jalap, mechoacan, and others of less importance. Many of the plants and fruits which are found in the country are common both to Chili and to Europe, and others that are carefully cultivated in Europe, grow naturally in this more favoured country. Chili has a variety of plants peculiar to it, of which about 3000 different species were collected by Molina. Among these were numerous flowers remarkable for their beauty and fragrance, and which, when they are in bloom, give the fields the appearance of so many parterres. Medicinal, dyeing, and aromatic plants, are also produced in great abundance. The different fruit trees, garden herbs, and flowers, which

Chili.

have been imported by the Spaniards from Europe, grow many of them even to greater perfection in Chili than in the countries to which they are indigenous. The vine produces in great abundance, and the soil appears to be peculiarly well adapted to it, as the thickets are filled with wild vines, from which the inhabitants contrive to obtain wine of a very good quality. But the cultivated vines are in the highest degree excellent, and the wine obtained from them is the best in Chili. It is in general red, and, in point of flavour, is not inferior to any European wine. The Muscadel wine, according to Ulloa, is of as good a quality as that which is made in Spain. The European fruit trees thrive equally well. In the southern provinces are forests of apple and quince trees from three to four leagues in extent, which produce fruit of excellent quality. The peaches amount to fourteen species, some of which weigh more than sixteen ounces, and the tree bears fruit twice in the year. Pears and cherries also produce two crops annually, but the latter growth rarely comes to great maturity. Oranges, lemons, and citrons, grow every where in the open fields, and besides the common lemon, a small species is produced, the fruit of which is about the size of a walnut, and very juicy. The olive, the first plant of which was carried from Andalusia to Peru in 1560, grows to great perfection; and Molina relates, that in the vicinity of St Iago he has seen olive trees three feet in diameter, and of a proportional height.

Mines.

Chili is rich in metallic wealth. It produces all the known kinds of the semimetals. These, however, are all neglected, with the exception of quicksilver, which it is necessary to procure for the refining of the precious metals. The two richest mines of this substance are in the provinces of Coquimbo and Copiapo, which might be rendered very productive if they were permitted to be worked. But the selling of quicksilver being a royal monopoly, the digging of it was rigorously prohibited, while Chili remained a colonial dependency of Spain. But if the present struggle for independence in which Chili, along with the other provinces of South America, is engaged in opposition to the mother country, shall terminate successfully, those arbitrary and absurd restrictions will naturally be superseded by a wiser and more equitable system.

Metals abound in all parts of the country. Lead is found of a good quality; and it is obtained in all the silver mines. All the lead mines also contain silver and gold; but in too small a quantity to excite the attention of the miners. The provinces of Coquimbo, Copiapo, Aconcagua, and Huilquilemu, contain very rich mines of iron; and the sand on different parts of the sea-shore, and on the borders of brooks and rivers, is replete with particles of this metal. In the true spirit of that tyrannical dominion which the Spanish government has always exercised over its colonies, those mines were prohibited from being worked, in order to favour the trade of the mother country, from which all the iron used in the colonies was imported, and thus the industry and resources of the immense regions of the new world were condemned to lie neglected and unproductive, under the pernicious thralldom of this absurd monopoly. In the course, however, of the last war between

the mother country and Great Britain, this metal rose to such an exorbitant price, that the native iron was secretly wrought; and it proved to be of an excellent quality. There are also abundant mines of tin, which is usually found in sandy mountains, under the appearance of black stones, very brittle and heavy. These mines are equally neglected with those of iron and lead.

From the conquest of the country to the present time, the mines of gold, silver, and copper, have occupied almost the undivided attention of the Spaniards. The copper mines are not confined to any particular district; but are found in all parts of the country. The richest mines are situated between the twenty-fourth and thirty-sixth degrees of latitude. The ore obtained from them is of every various quality, and it usually contains a proportion of gold which varies from one-tenth to one-third. Some of the ores which are rich in metal, are considered of no value from the expence of refining them; those generally wrought are the grey, or bell-metal ore, and the malleable copper. The grey ore, or bell-metal, is usually mineralized with arsenic and sulphur, and contains a small mixture of tin. From this mixture, and its grey colour, which it retains even after it is melted and refined, Molina considers it as a species of native bronze, which metal it also resembles in its brittleness. Its specific gravity, when artificially combined, is however greater than that of any one of the metals of which it is composed. The malleable copper, which abounds in different provinces, possesses all the usual properties of that metal, and is found mineralized with a small portion of sulphur, which the simple process of roasting is sufficient to expel, and to render the metal fit for use. The miners, however, refine it in the usual manner, from a notion that it improves the metal in brightness. The malleable copper is always found combined with gold, and veins of pure gold are frequently found in the deepest copper mines. Between the cities of Coquimbo and Copiapo, the number of copper mines which are worked amount to one thousand; many more have been opened. But those only are worked, of which the ore is so rich as to yield half its weight in refined copper. The most celebrated copper mine in Chili was that of Payen, the working of which was relinquished in consequence of the hostility of the native tribes who inhabited the district. Pieces of pure copper, from 50 to 100 weight, were frequently found in this mine. Another equally rich mine has since been discovered at Curico. The ore consists of gold and copper in equal proportions, and has an uncommonly brilliant appearance from the particles of this precious metal with which it is filled. The quantity of copper annually extracted from the mines of Chili, cannot be ascertained with any exactness. It is conjectured by Molina, that about 100,000 quintals (of 1600 ounces each) are annually imported to Spain. Great quantities are also sent to Buenos Ayres, and about 30,000 quintals are annually sent to Peru, besides what is used for domestic purposes.

The silver mines of Chili are found in the highest and coldest parts of the Andes; and various mines, though rich in ore, have, on this account, been abandoned from the difficulty and expence of work-

Chili.

Chili. ing them. The richest are those of St Iago, Aconcagua, Coquimbo, and Copiapo. In these the silver is frequently found pure; it is also found in various sorts of ores mineralized with sulphur and arsenic. The mine of Uspallata, situated in the 33d degree of south latitude, and so named from the plain of that name, is the most productive. There are three species of ores yielded by this mine which have been found, from assays made at Lima, to yield 200, 50, and 14 marks *per* caxon, which is equal to about 1 in 38, 1 in 154, and 1 in 548.

Gold is, of all the metals, most abundant in Chili, and, in some parts of the country, there is scarcely a mountain which does not contain it in a greater or less degree. It is found also in the sands of the plains, and is washed down from the mountains by the brooks and rivers. In the southern provinces, between the river Biobio and the archipelago of Chiloe, several productive mines were formerly discovered. But since the expulsion of the Spaniards from this quarter by the Araucanians, the warlike inhabitants of the country, these mines have been in their possession, and they have prohibited them from being opened. The most important mines which are at present wrought, are those of Copiapo, Guase, Coquimbo, Petorca, Ligua, Tiltil, Putaendo, Caen, Alhue, Chibato, and Huilli-patagua. All these, with the exception of the three last, have been wrought ever since the conquest of the country by the Spaniards, and have been found very productive. The substances in which gold is found are

variable, and there is no kind of stone or earth which may not be said occasionally to serve as a matrix for this precious metal. It is most frequently found in a very brittle red clay stone, and is to be seen in small grains or brilliant spangles under singular forms, or in irregular masses that may be cut with a chisel. The mines are worked either with the pick-axe or by explosion, according to circumstances. The rock in which the ore is found being then reduced to powder by a mill of a simple construction, the gold is extracted by the common process of amalgamation with mercury. Gold is also procured by the washing of the auriferous sands. But this method is only practised by the poorer classes, who cannot afford the expences of regular mining. The quantity of the gold annually found in Chili, which pays the royal duty of one-fifth, is estimated by Molina to amount in value to four millions of dollars. A million and a half is coined at the mint of St Iago; the remainder is exported in bullion, or is used in the country for plate and jewellery. There is besides a considerable quantity smuggled.

Animals. Chili is not so abundant in animals as some of the other countries of America. The indigenous quadrupeds hitherto discovered amount to 36 species; but it is the opinion of Molina, that, in the unexplored and desert regions of the Andes, many others exist which are hitherto undiscovered, or imperfectly known. Of the species peculiar to Chili, the most remarkable is the vicunna, or the guanaco, sometimes called the American camel, from its resemblance to that animal in shape; although it differs from it in another essential quality, namely, that, while the camel is fitted by its constitution to live in the most

Chili. parched and sultry deserts, the vicunna is most vigorous and thriving in the inclement regions of the higher Andes, amid ice and everlasting snow. The lama, or Peruvian sheep, is also found in the Andes of Chili. The other animals are the wild goat, the dog, the fox, and the pugi, or lion, which animal it resembles in its size and roaring, though it is destitute of mane. All the European animals have been carried to Chili, where they have multiplied exceedingly, and some of them have even increased in size. The birds are very numerous, amounting, those that belong to the land, to 135 species, while it is impossible to enumerate all the different species of sea-birds. There are but few reptiles, and the insects are less numerous than in some of the southern countries of Europe. The coasts of Chili abound with various kinds of excellent fish, of which the different species are calculated to amount to 76, most of which differ from those found in the northern hemisphere, and appear to be peculiar to that sea. The bays, harbours, and in a particular manner the mouths of the large rivers, swarm with them, and in many places they are caught with very little trouble. The fresh waters also abound in fish, especially those which are beyond the 34th degree of south latitude.

The population of Chili is composed of Europeans, Creoles, Indians, Negroes, and Mestizoes. Of these the Creoles form the most numerous class. There exist no data for a general enumeration of the population; but it is certain that the country is very thinly stocked with inhabitants, in proportion to its fertility.

The domestic tranquillity of Chili has been seldom disturbed since its original conquest, except by the wars continually waged between the Spaniards and the tribes of Indian natives, many of whom still continue to enjoy their barbarous independence, and to defy the utmost efforts of the Spanish arms. But about the year 1810, when the French had nearly effected the conquest of the mother country, the Chilian, along with the other provinces of Spanish America, began to take measures for establishing their independence. At first affairs seemed to wear the appearance of unanimity and peace. The authority of the mother country was quietly superseded by the aristocracy of the colony, and the government passed into the hands of the great Creole families. Since this period, Chili appears to have been subjected by the royal armies; but lately it has been restored to independence by a detachment from the army of Buenos Ayres, under San Martin, who, having defeated the royal troops in several engagements, has made himself master of all the most important places of the country. The accounts hitherto received in Europe of these events are too partial and contradictory to enable as to enter at present into any detailed or connected narrative of them. But an opportunity will occur in the general article of SOUTH AMERICA, for a full account of the great revolution which has taken place in this continent.

See *History of Chili*, by Don Ignatius Molina, 1809.—*Travels from Buenos Ayres by Potosi to Lima*, by A. T. Helms, 1807.—*Edinburgh Review*, Vol. XIX. (6.)

CHINA.

China.

If the embassy of the Earl Macartney to the Court of Pekin failed in its immediate object, which was just about as reasonable as if the Emperor of China had sent to demand from us the cession of the Isle of Wight, it succeeded at least in throwing a more clear and distinct light on the nature of the government, the laws, language, and literature, of one of the most ancient, and most extensive, and, beyond comparison, the most populous nation of the world. It was the means of obtaining a nearer insight into the manners of the people, and of forming a more correct estimate of their moral character, than had hitherto been given in the prejudiced accounts of the Romish Missionaries. But the most important acquisition which resulted from this embassy, in a literary point of view, was, the complete development of the extraordinary language of the Chinese, which the Jesuits had invariably represented as of so obscure and mysterious a nature, that the whole period of human existence was too short to acquire even a competent knowledge of it; whereas we now know that a moderate degree of application for two or three years, with the assistance of a Chinese, will enable the student to write it with ease, to read and translate their most obscure books, and to transact every kind of business, commercial or political; and that this knowledge has opened up a vast fund of literature which, in Europe, was hardly suspected to exist. To Sir George Staunton, in the first place, to Dr Marshman and his son, at Serampore, to Mr Morrison, a Missionary at Canton, and to Mr Davis, a promising youth in the East India Company's Factory at that port, we are more indebted for a true and distinct state of the laws, the language, the institutions, and literature of China, than to all the voluminous writings of the Jesuits, which, however curious and valuable in many details, are crowded with errors and exaggerations. These pious men, under the influence of bigotry and prejudice, have left untouched, or misrepresented, or wrapt up in mystery, many subjects of considerable interest in a religious, political, and moral point of view; nor are they without excuse. They entered China at a time when the comforts and conveniences of life were but little known in Europe, and still less to them, whose knowledge extended not beyond the boundary wall of their respective monasteries; they were flattered, also, by the reception they met with from the sovereign of so vast and powerful an empire—circumstances which naturally disposed them to exaggerate the moral and political virtues of the people among whom they had voluntarily domiciliated themselves for life. There was enough, however, to excite their admiration. A country swarming with a population, which for ages had kept itself wholly unmixed with the rest of the world,—whose language, laws, and institutions, had no analogy with those of any known nation, and had suffered no change—to whom

the art of printing was known and freely practised, without licence or previous restraint, for centuries before the dark ages overshadowed Europe; who were clothed in silk and cotton garments, when Europeans had only skins to cover them with; and who were acquainted with most of the useful arts and manufactures, at a period long antecedent to the Christian era. Such a people, inferior as they now may be in science and civil liberty to some of the nations of Europe, could not be regarded with indifference, but had then in particular, as they still continue to have, powerful claims to the attention of mankind. By combining and comparing these early accounts with more recent materials, and by the help of some small personal information, we may be enabled to make some additions to, as well as to correct some inaccuracies in, the Article on CHINA in the body of the *Encyclopædia*.

The conterminous empires of Russia and China occupy between them about one-fifth part of the habitable globe, in pretty nearly equal portions; but the population of the latter is about four times greater than that of the former, even after including its recent addition of ten millions of Poles. We can easily trace the boundaries and mark the extreme limits of these two great empires, by parallels of latitude and meridional lines of longitude; but when we come to reduce them to square miles, or speak of their contents in acres, the mind is bewildered in the magnitude of the numbers required to express them, and forms but an indistinct idea of their superficial extent. For this reason we shall content ourselves by merely tracing the boundary lines.

The frontier of China, on the side of Russia, including every part of Tartary under its immediate protection, and from which it derives a tribute, is as under: Commencing at the north-eastern extremity, where the Uda falls into the sea of Otchotsk, in the 55th parallel of northern latitude, it stretches west, and W. S. W. along the limits of the Tungousi Tartars, the Duourian Mountains, along the Kerlon, which divides it from the Russian province of Nertchinsk, till it meets the 50th parallel. It then continues along that parallel from 117° to 70° of E. longitude, separated from Tobolsk and Irchutsk by the Sawansk, the Altai, and the Bercha mountains. On this line, and about the 106th meridian, on the river Selenga, are situated the two frontier trading towns of Kiackta and Mai-mai-tchin, the only two points in the long conterminous line of boundary where Russians and Chinese have any communication. From hence, descending south along the Kirghis Tartars, Western Toorkistan, and Little Thibet, it is terminated in this direction by the Hindoo Coosh; and turning to the S. E. along the Himalah Mountains, Bootan, Assam, the Burman Empire, and Tunquin, it again skirts the sea in the parallel of 21° as far to the eastward as 123° (in-

China.

Boundaries.

China:

cluding Corea, to 130°, and near the Uda, from whence we set out, to 143° of E. longitude. Yet in all this extent of frontier, which cannot be less than 10,000 geographical miles, the Chinese territory has hitherto preserved itself so invulnerable, and even inaccessible to foreigners, that not a Russian, a Turcoman, an Afghaan, a Hindoo, Burman, or Tunquinese, by land, nor an European nor an American, among the numbers that annually proceed to Canton for the purposes of trade, have at any time been able to transgress any part of this most extensive boundary, without the knowledge and permission of its vigilant and jealous government; aided, however, by a moral barrier, of itself perhaps insuperable,—the impossibility of communication, from the total ignorance which prevails, from the highest to the lowest of the people, of every language but their own, and the unaccountable ignorance of other nations of *their* language. A singular instance may here be mentioned of the inviolability of the frontier, notwithstanding the perseverance of the individual who attempted it, from the unwearied vigilance of the government. Mr Manning, an English gentleman of property and education, went to Canton many years ago, with the view of proceeding into the interior of China, and of domesticating himself for some time with the people. On his arrival there he adopted the Chinese dress, suffered his beard to grow, and sedulously applied himself to the study of the language, both written and spoken. When the time approached that his appearance, manners, and language were considered to be sufficiently Chinese to escape detection, it was communicated to him, by a sort of demi-official message, that his intentions were known, and that it would be in vain for him to make the attempt, as measures had been taken to make it impossible for him to enter the Chinese territories beyond the limits of the English factory. He alleged that his views were innocent, that he was simply an individual, urged solely by curiosity and a desire to mix among the people, and to witness the happy condition of this far-famed nation, wholly unconnected with any political, commercial, or religious views,—and he particularly urged, that he was no missionary of any kind, as those of that character had of late given uneasiness to the government,—but he urged his suit in vain. He next tried Cochin-China, but with no better success; the same kind of political jealousy prevailing in that country as in China. Determined, however, not to be thwarted in his object, he proceeded to Calcutta, travelled to the northern frontier of Bengal, found means to penetrate through Bootan to Lassa in Thibet, and was on the point of realizing his long deferred hope by a journey along the Tartar frontier to the capital of China, when he was detected by the Chinese authorities, and ordered immediately to quit the country—so utterly impossible is it to deceive this watchful government. With regard to their own people, the laws are strict, and remarkably severe against any one who shall secretly or fraudulently pass the barrier; and if any individual communicate with foreign nations beyond the boundaries, the penalty is death by strangulation.

This interdiction of intercourse with a people who

have nothing in common with the rest of the world, will account for the total ignorance that so long prevailed, and the little knowledge we yet possess, respecting this singular and original people; for that they are an original and unmixed race we conceive no reasonable doubt can be entertained, though a different hypothesis has been held by learned and ingenious men. By De Guignes and Fréret, arguing from the communications of the Jesuits, they were supposed to be derived from a colony of Egyptians; by the earlier Jesuits they were set down as a tribe of the Jews; and by Sir William Jones as the descendants of the Cahantrya or Military Caste of Hindoos, called Chinas, “who,” say the pundits, “abandoned the ordinances of the Veda, and lived in a state of degradation.” With submission to such high authorities, we should as soon think of deriving the trunk of a tree from its branches, as the people of China from any of these. That they are not Egyptians, the ingenious Pauw has most clearly and satisfactorily demonstrated, by proving that, in no one iota, does there, or ever did there, exist one single resemblance. As little similarity is there between them and the Hindoos; no two people, indeed, could possibly differ more than they do in their physical and moral character, in their language, and in their political and religious institutions. The colour of the Hindoo is ebony black or a deep bronze; that of a Chinese a sickly white, or pale yellow, like that of a faded leaf, or the root of rhubarb;—the features of a Hindoo are regular and placid; those of a Chinese wild, irregular, constant only in the oblique and elongated eye, and the broad root of the nose;—the Hindoos are slaves and martyrs to religious ordinances; the Chinese have superstitions enough, but, strictly speaking, no religious prejudices;—the Hindoos are divided into castes; the Chinese know of no such division;—the historical records of China go far beyond the time that these supposed Chinas, of Sir William Jones, peopled the country; the Hindoos have not a page of history;—the language of Hindostan is alphabetic; that of China a transition from the hieroglyphic to the symbolic; and there is not the slightest analogy in the colloquial languages of the two countries. But Sir William Jones had a theory to support, which made him overlook many inconsistencies; and he had no knowledge of the Chinese language. The name of Chinas seems to have caught him, a name, however, utterly unknown to the Chinese themselves. The madman, who, in the third century before Christ, is accused of burning all their books, but who conquered the revolted provinces and reunited them to the empire, endeavoured to give to China the name of his own dynasty, *Tsin*, which might have been known to the Hindoos, and, through them, to the Arabs, from whom Europeans had their *Sina* and *China*; but this dynasty, if we take Sir William Jones's dates, reigned a full thousand years subsequent to the supposed emigration of the Chinas. The most ancient name for China, which is still in use, is *Tien-sha*, under heaven, or inferior only to heaven, but the most common appellation is *Tchung-quo*, the middle kingdom: and here it may be pro-

nese.

Inviolability
of the
Frontier.

China. per to observe, that this name is not given, as the French missionaries would lead us to suppose, from a notion, among this people, that China is placed on the middle of the earth's square surface, but from the circumstance of the Emperor Tching-whang having fixed his court at Lo-yang, in the province of Ho-nan, when he gave to this capital the name of *Chung-quo*, the middle of the kingdom, which, in fact, is nearly the truth, and this name was afterwards transferred to the whole empire.

Dr Marshman has set the question, as to any similarity between the Sanscrit and Chinese languages, completely at rest. The priests of Budh, who were permitted to enter China in the first century of the Christian era, endeavoured, with their religion; to introduce the Sanscrit alphabet, or series of sounds represented by the Devanagari character, and this series being placed at the head of *Canghe's Dictionary*, induced Dr Marshman to suppose, that there might be some connection between the Chinese and the Sanscrit languages; had he, however, read the preface to that dictionary, he would have seen, that the compilers announce it as a system brought from the West, which the learned of China could never be prevailed on to adopt. This Hindoo series of alphabetic sounds did not, however, mislead him; he was fully aware that a pure, unchangeable, monosyllabic language, could not arise out of a polysyllabic one; that a language which admitted of no change from its original monosyllabic root, but retained it in its primitive form, whether employed as a noun, a verb, or a participle, could not have been derived from another language whose dhatoos or roots, by a complicated mechanism, assumed a hundred different shapes; nay, whose inflections, in some instances, are so numerous, as to produce more than a thousand modifications of an idea from one radical word. Added to all which, when he reflected that there were in the Sanscrit alphabet four or five sounds which the organs of a Chinese could not by any possibility enumerate, he found it utterly incompatible to associate the two languages together, and was confirmed in his idea by the test of facts. He took the *Ramayana*, which is supposed to be the most ancient poetry in the Sanscrit language, and the *Shee-king* of the Chinese; in ten pages of the former, containing four hundred and fifty-nine words, he found only thirteen monosyllables, and of these thirteen, seven do not occur in the *Shee*, nor are any two of them used to express the same idea in both languages. He next took four pages of the *Mahabharu*, in the Bengalee dialect, containing two hundred and sixty-five words, in which he found only seven monosyllables, and of these three only were Chinese.

Proceeding in the same manner, he proves, what was scarcely necessary, that there exists not the most distant resemblance between the Chinese and the Hebrew languages. In examining the speech of Judah to Joseph, in the 44th chapter of Genesis, he finds it to contain two hundred and six words, in which there occur sixteen monosyllables, but of these seven only are Chinese words. In Abraham's intercession for Sodom, out of two hundred and thirty words, ten

only are monosyllables, and of these four are Chinese. Again, in the maledictory prophecy of Noah, relative to his grandson Canaan, in twenty-six words there is but one monosyllable. It would be most absurd, therefore, to conclude, that the Chinese derived their language from the Hebrew, when one word only occurs out of twenty-nine, as in the first example,—one out of fifty, as in the second,—or one in twenty-six, as in the third; and he thinks it more rational to infer, that, as it is neither derived from the Sanscrit nor the Hebrew, it is an original language, invented by themselves. Neither is there any resemblance to be found in the manners, customs, physical character, or religious creeds of the two people. There are, in fact, a colony of Jews in China, whose entrance can be traced beyond the Christian era; who use the Hebrew language; who abstain from swine's flesh, the great article of Chinese food; use circumcision, and celebrate the Passover, neither of which the Chinese know any thing about; and it may, therefore, fairly be concluded, that they are neither Jews, Hindoos, nor Egyptians, but an original people, who have kept themselves more unmixed with other nations than any people existing on the face of the earth. (*Barrow's Travels in China. Marshman's Clavis Sinica.*)

Pauw, and some other writers, are of opinion, that they proceeded originally from the heights of Tartary. It is, in fact, obvious enough, that the Tartars and Chinese are one and the same race; and the only question seems to be, whether the latter, guided by the mountain-streams, descended from the bleak and barren elevations of Tartary, which, bulging out of the general surface of the earth, have been compared with the boss of a shield, to the fertile plains and temperate climate of China? or, whether the former are swarms sent off by an over-abundant population, and driven into the mountains? The former supposition will be regarded, perhaps, as the more probable of the two. In all the institutions which the change from a pastoral to an agricultural state would necessarily require, the ancient manners and customs of the Hyperborean Scythians, as described by Herodotus, are still discernible among the Chinese. A Chinese city is nothing more than a Tartar camp, surrounded by mounds of earth, to preserve themselves and cattle from the depredations of neighbouring tribes, and nocturnal attacks of wolves and other wild beasts; and a Chinese habitation, the Tartar tent, with its sweeping roof supported by poles, excepting that the Chinese have cased their walls with brick, and tiled the roofs of their houses. When the famous barbarian Gengis-Khan made an irruption into the fertile plains of China, and took possession of a Chinese city, his soldiers immediately set about pulling down the four walls of the houses, leaving the overhanging roofs supported on the wooden columns, by which they were converted into excellent tents for themselves and horses. Yet such is the facility with which Chinese and Tartars amalgamate, that although this celebrated barbarian could neither read nor write any language, he listened to the advice of the conquered,—became sensible of the change of situation in which he found him-

China.

China.

self,—did every thing he could to repair the errors he had committed,—and both he and his successors left good names behind them in the annals of the country. In like manner the present Mantchoo Tartars, who lived in tents, and subsisted on their cattle and by hunting, immediately accommodated themselves to the manners, the customs, and the institutions of China, preserving nothing of their own, not even their religion, and scarcely a vestige of ancient superstitions that do not coincide with those of the Chinese,—one of the most singular of which is, their agreement in the birth of man and of the serpent-woman, and the universal use and estimation of the ancient Scythian emblem of the dragon. Next to the Chinese, the Turks seem to have preserved most of the character and customs of the ancient Scythians from whence they sprung, and the Turks are Tartars. Some German author has pointed out a similarity between the Turks and Chinese in seventeen different customs; he might have extended the parallel to more than twice that number.—(*Recherches sur les Chinois, &c.* par M. de Pauw.)

Antiquity and History.

It has long been objected in Europe against the authenticity of the early part of Chinese history, that it abounds with absurd fictions and irreconcilable contradictions; and that it sets up a chronology and cosmogony at variance with the sacred writings, and the generally received opinions of mankind. This, however, is not the fact with regard to Chinese history in its pure and original state, divested of the reveries of Fo or Budh, which the priests of this sect imported with their religion, and found means to propagate among the vulgar. The Hindoo periods of the creation and destruction of the universe,—the miraculous conceptions,—and all the absurd stories of gods, demi-gods, and heroes, are scouted by the learned of China. The period they assign for the commencement of their civilization, is perfectly consistent with the time when, according to holy writ, the great catastrophe befel the earth; and though they are unable to establish the truth of the early part of it by any concurring contemporaneous histories of other countries, yet neither can any extraneous authority be produced to contradict theirs; the probability, therefore, of the truth or falsehood, must rest on the internal evidence of their own history, and the manner in which that history has been compiled, preserved, and handed down to posterity.

We may take it for granted, that when the Emperor Kaung-hee summoned to Peking the most learned men of the empire, for the purpose of translating into the Mantchoo language an abridged history of China, from the earliest times, those annals only were consulted which were considered most authentic, namely, those which are compiled and published by the college of *Han-lin*. Pere Mailla was one of those missionaries who viewed the Chinese through the eye of prejudice less than most of the Jesuits. He was employed by the Emperor in making a survey of the empire, which cost him and his colleagues the labour of ten years; he passed forty-five years of his life in the country, and generally about the court, during which time he made himself perfectly acquainted with the Mantchoo and the Chinese languages. When, therefore, Kaung-hee undertook the

China.

laudable design of giving to his Mantchoo subjects an authenticated history of China in their own language, Pere Mailla conceived the idea of proceeding *pari passu* with a translation of the same work into French; and having lived to complete this Herculean labour, it was published at Paris, after many difficulties and delays, by the Abbé Grozier, in fourteen large quarto volumes, under the title of "*Histoire Generale de la Chine*."

The history of China commences, in fact, at a period not much more than 3000 years before the birth of Christ, by describing the little horde, from whence the Chinese had their origin, to be in as barbarous and savage a state as can well be imagined; roving among the forests of *Shen-see*, just at the foot of the Tartar mountains,—without houses,—without any clothing but the skins of animals,—without fire to dress their victuals,—subsisting on the spoils of the chase, on roots and insects. Their chief, of the name of *Yoo-tsou-she*, induced them to settle on this spot, and they made themselves huts of the boughs of trees. Under the next chief, *Swee-gin-shee*, the grand discovery of fire was effected, by the accidental friction of two pieces of dry wood. He taught the people to look up to *Tien*, the great creating, preserving, and destroying power; and he invented a method of registering time and events, by making certain knots on thongs or cords twisted out of the bark of trees. Next to him followed *Fo-hee*, who separated the people into classes or tribes, giving to each a particular name; discovered iron; appointed certain days to show their gratitude to heaven, by offering the first fruits of the earth; and invented the *Ye-king* or *Koua*, which superseded the knotted cords. *Fo-hee* reigned 115 years, and his tomb is shown at *Tchin-choo*, in the province of *Shen-see*, at this day. His successor, *Chin-nong*, invented the plough, and from that moment the civilization of China proceeds by rapid but progressive steps.

As the early history of every ancient people is more or less vitiated by fable, we ought not to be more fastidious or less indulgent towards the marvellous in that of China, than we are towards Egyptian, Greek, or Roman history. The main facts may be true, though the details are incorrect; and though the accidental discovery of fire may not have happened under *Swee-gin-shee*, yet it probably was first communicated by the friction of two sticks, which, at this day, is a common method among almost all savages of producing fire. Nor is it perhaps strictly correct that *Fo-hee* made the accidental discovery of iron, by having burnt a quantity of wood on a brown earth, any more than that the Phenicians discovered the mode of making glass by burning green wood on sand; yet there is nothing improbable, neither in the one nor the other, that these two processes first led to the discovery of both. And if it be objected against the history, that the reign of a hundred and fifteen years exceeds the usual period of human existence, it should be recollected, at the same time, that such an instance is as nothing, when compared with those contemporaneous ones recorded in biblical history. Thus also considerable allowances are to be deducted from the scientific discoveries of *Chin-nong* in botany, when we read of

China.

his having in one day discovered no less than seventy different species of plants that were of a poisonous nature, and seventy others that were antidotes against their baneful effects.

The next sovereign, Hoang-tee, was an usurper; but during his reign the Chinese are stated to have made a very rapid progress in the arts and conveniences of civilized life; and to his lady, See-ling-shee, is ascribed the honour of having first observed the silk produced by the worms, of unravelling their cocoons, and working the fine filaments into a web of cloth. The tomb of Hoang-tee is also kept up to this day in the province of Shen-see.

From these few recorded facts, out of a multitude stated by Chinese historians, we think it may be inferred, that at a very distant period, and at the earliest dawn of civilization, a small horde of Tartars, descending from their elevated regions, seated themselves on the plains of Shen-see, at the foot of the mountains; and, under the guidance of a succession of intelligent chiefs, changed the pastoral and venatorial life for one more stationary, and at length became cultivators of the soil, and spread themselves over the fine fertile regions, now known by the name of China. (*Hist. Gen. de la Chine*, par P. Mailla.)

Authenticity of their History examined.

Some doubts have been entertained with regard to the authenticity of that part of Chinese history which relates to the reign of the three first sovereigns, *Fo-he*, *Chin-nong*, and *Hoang-tee*, which is supposed to have been contained in a book called the *San-fen*; and of the five following reigns, ending with the joint government of *Yao* and *Chun*, as detailed in another work named the *Ou-tien*. Of the first of these works the Chinese avow that nothing is known; and all that remained of the second was an imperfect fragment preserved by being inserted at the head of one of their most ancient and most valued books, called the *Shoo-king*, of which we have a translation, or rather a bad paraphrase, by Pere Gaubil. This fragment relates chiefly to the reign of *Yao* and *Chun*. The rest of the *Shoo-king* contains an abridged history of the empire from the joint reign of these two sovereigns, down to the time of Confucius,—being a compilation by this celebrated sage. The authenticity of the *Shoo-king* must, however, depend on two circumstances; first, whether it is the same that was composed by Confucius; and, secondly, whether the materials which this sage possessed were authentic. If he really had copies of the *San-fen* and *Ou-tien*, the *Shoo-king* may fairly be classed with the history of Herodotus, with whom Confucius was contemporary,—the Chinese historian having the additional advantage of previous written records. But, admitting this to have been the case, there is still an awkward and suspicious chasm in the history of China, the cause of which draws largely on our faith. The Emperor Che-whang-tee, of the dynasty of *Tsin*, after reducing, as we before observed, the refractory provinces, conceived the mad scheme of destroying all the writings of the empire, under the idea of commencing a new set of annals with his own reign, in order that posterity might consider him as the founder of the empire. Some sixty years after this barbarous decree had been carried into execution, his successor, desirous

China

as far as might be possible to repair the injury, held out great rewards to those who could produce any part of the annals of the empire, more especially the hundred chapters of the *Shoo-king*. After some time a copy of the *Shoo-king* was procured in this manner. All ancient writings, and those of Confucius in particular, were comprised in short sentences, forming a kind of poetry, not unlike the Proverbs of Solomon; and they were in the memory of most persons then, as they are now, who had any pretensions to literature; but sixty years having been suffered to elapse before any encouragement was held forth for the revival of letters, most of those who had known the *Shoo-king* were either dead, or so old as to have lost the recollection of it. At length, however, a man named Foo-seng, of the age of ninety and upwards, was discovered, who, in earlier life, could repeat the whole *Shoo-king* by heart. To this man the historiographers of the empire were sent: but his articulation was so imperfect, and he was unable to write, that the parts of it which he recollected could only be obtained through the medium of his daughter, who, having received the words from her father, repeated them to the historians. In this way they proceeded, until twenty-nine of the books or sections of the *Shoo-king* had been committed to writing, which Foo-seng had comprehended in twenty-five; but here they were compelled to stop, the infirmities of Foo-seng not allowing him to proceed. A document thus obtained, did not pass for genuine among the learned; yet all were eager to procure copies of it, to compare such passages as each might recollect to have heard their fathers repeat. The early annals of China, however, do not rest solely on this record. Half a century after this, a prince of Loo, in pulling down an old building (some say the house in which Confucius lived), to erect on its site a temple in honour of that philosopher, discovered in one of the walls an imperfect copy of the *Shoo-king*, with two other works of Confucius. They were much devoured by the worms, and written in a character which had gone out of use. The learned men were assembled to collate this newly discovered copy with that taken from Foo-seng's recollection, and it is said that they did not materially differ, except in the division into chapters. They therefore proceeded in decyphering the remaining part of the characters, and, after much time and labour, obtained twenty-nine complete articles, in addition to the twenty-nine recollected by Foo-seng, making the fifty-eight chapters of which the *Shoo-king* at the present day is composed.

The story is told by Chinese writers with some variations; but it is a common saying, that "both the ancient and modern *Shoo-king* were taken from the wall of a house." According to some, the old man Foo-seng hid a copy of the book within the wall of his house, and, to avoid the rigour of the persecution that was carried on against men of letters, put out his own eyes and affected idiotism. The whole story, however, is not very consistent, and it has been conjectured that it was invented as a salvo to the mortified vanity of the Chinese, who were unable to make out a connected series of annals from a high antiquity; and that, in fact, Confucius was

China. the first regular historian of the empire, and probably the person who first led them on rapidly to a state of civilization. One thing, at least, is perfectly well ascertained; no writings of any description prior to those ascribed to Confucius, exist in China. Where the *Shoo-king* terminated, Confucius commenced his own annals, called the *Tchun-iou*, which carried down the history of the empire to his own time, and, of this work, a copy had been secreted by one of the historiographers. Many other manuscripts were from time to time brought in, from which were selected all that belonged to the history of the empire, by a commission, of which *Tse-ma-tsin* was placed at the head; after his death, his son *Tse-ma-tsien* completed this great work about a century before the Christian era, which is still extant, and its author considered and known by the name of the *Restorer of History*. From that period to the present time, there seems to be no reason to doubt the authenticity of Chinese history, or to accuse it of undue partiality. The history of a dynasty is not made public from authority, until that dynasty has ceased to reign; and it does not appear that any injustice is done or attempted by the succeeding dynasty. Some of the atrocities of Genghis Khan are related on his first incursion into China, but ample justice is done to him and to his successors. And the present Tartar dynasty, in publishing the annals of that of *Ming*, whom they displaced, does not appear to have done it any violent injustice. This event occurred under the eye of several European missionaries, then resident in the capital; and, by their concurring testimonies, the affairs of the empire were left, as the Chinese state, to priests, and eunuchs, and jugglers; and it is favourable to the character of the college of Han-lin, that, for the sake of accuracy, the history of the dynasty of *Ming* was retarded for some time by the Chinese members refusing to allow the Tartar race, then on the throne, the title of *imperial*, until the last remaining prince of the family of *Ming* should be extinct; but the Tartars insisted on dating the commencement of their own dynasty from the day they were in possession of Peking; to which at length the Chinese members were reluctantly compelled to assent. In the instance of Genghis-khan, they were more successful. The name of this marauder does not appear in the list of Chinese Emperors, nor those of the two next in succession, Ogdai-khan, and Menko-khan, though their exploits are amply detailed in Chinese history. The Mongoo dynasty commences only with Kublai-khan, who was not declared emperor till the death of the last remaining branch of the family of *Song*. Their account of these Tartars is probably very correct. They had neither treasure to pay their troops, nor magazines of provisions for their subsistence. They lived by the chase and by plunder, driving before them large herds of cattle, whose flesh served them for food when other supplies failed, and their skins for clothing. They put to death men, women, and children, without compunction, plundering the towns and villages through which they passed, and carrying off the young women; and when the Chinese took up a strong position in the passes of the mountains, it was the practice of Gen-

gis-khan to seize all the old men, women, and children of the neighbouring country, and drive them forward at the head of his army, and thus approaching the Chinese under cover of their own friends and relations, succeed in coming upon them without their being able to strike a single blow. And it is added, that, had it not been for the remonstrances of a Chinese who had united his fortunes to those of the invaders, Genghis-khan had determined to put to death all the agriculturists for plowing up the ground and destroying the grass, on which his numerous cavalry was to be subsisted.

As their history relates solely to the internal events and transactions of the empire, and as their policy has been to exclude all communication with foreign nations, we have no means of verifying the facts that are related; but it is in favour of their accuracy to find a fact recorded in the progress of a revolution brought about by a change of dynasty, which is also related by an European traveller, who was himself a party in the transaction, and who is worthy of implicit credit in all that he states to have fallen under his own knowledge and observation. Marco Polo states, that *Sian-foo* was taken by the Mongoos after a siege of three years, chiefly by the means of machines made by his father and uncle, which hurled stones of three hundred pounds in weight; and it is recorded in the history of China, that the city of *Siang-yang* held out against the troops of Koublai-khan for four years, but was at length reduced by means of certain machines for hurling stones of an extraordinary weight, constructed by one *Alihaya*, who had travelled to China from the western countries.

Another instance of the fidelity of the Chinese historians is affirmed by the faithful traveller Marco Polo. It is recorded that Kublai-khan adopted the Chinese manners and customs, and gave encouragement to the arts and sciences, commerce and manufactures; that he opened the ports of China to all foreigners; that he sent embassies and expeditions to almost every part of the world, and received tribute from the sovereigns of Pung-kia-la (Bengal), Soo-ma-ta-la (Sumatra), and Mal-la-kia (Malacca); subdued Corea, but failed in his expedition against Japan, or, as they call it, Ge-pun-quo, the kingdom of the rising sun; all of which will be found related in Marco Polo; whose accuracy in relating what was told him, appears in another Chinese book called *Fo-quo-kee*, a history of the kingdom of Fo, giving an account of the temples of India, visited by a Hochang or priest, in the fourth century, in which, among other things, is noticed the yells and musical strains made by invisible spirits in the great desert of Sha-moo, to frighten and bewilder the traveller; a fable repeated by Marco Polo, in speaking of the same desert, nine hundred years afterwards (*Hist. Gen.*; Morrison's *Dictionary*; Marco Polo.)

But whether the ancient history of China be true Government, or false, whether Yao or Chun were real or fictitious personages, and Confucius the real author of the religious, moral, and political maxims ascribed to these sovereigns, the Chinese at least entertain no doubts on the subject; and on these maxims are all their

China. institutions founded, as we find them existing at the present day. In all these institutions may be discovered the traces of a primæval state of society. The leading features of the government still wear the stamp of the first rude attempts to restrain savage man within the pale of social life; paternal solicitude and protection on the part of the chief; obedience and service on that of the people. The same principles which their history states to have regulated the pastoral tribes of Fo-hee on the plains of Shen-see, 4000 years ago, actuate the measures of the Chinese government of the present day. A few modifications of the ancient patriarchal system has served to convert tribes of hunters and shepherds into a nation of agriculturists, and kept them so; for of all governments that the history of the world has made known, none have had that permanency and stability which China has enjoyed. Like other governments, the machine may occasionally have been enlarged; a few wheels may have been added; its movements sometimes disturbed; its operations impeded; and a spring or a wheel injured or destroyed; but the damage has soon been repaired, and without altering or improving the principles of the construction. Rebellion, revolution, and foreign conquest, have occasionally removed old families from, and placed new ones on, the vacant throne; and for a moment disturbed the movements of the machine, but a little time has generally restored the usual harmony of its operations. It becomes, therefore, an object of interest to inquire, on what principles and by what practice, the largest mass of population, which in any age or country has been united under one government, has been kept together in one bond of union, for a period of time extending far beyond that at which the history of the earliest European nations may be said to commence. It has assuredly not been owing to the superior virtues of its princes; for China has had its Neros and Caligulas as well as Rome; nor to the superior virtues of the people; for Chinese morality consists more in profession than in practice; and yet the affectation of superior virtues in the one, and of moral sentiment in the other, have gone far in giving support to the system of government and securing the permanency of the ancient institutions of the country.

Ancient usage, universally appealed to, is almost the only rule of conduct, and the only limitation or control prescribed to the executive authority vested in the monarch. The public voice is never heard, but the public opinion is sedulously courted by the sovereign, and conveyed to every part of the empire through the medium of the *Pekin Gazette*. This vehicle of imperial panegyric is published daily; it is sent forth into all the provinces, and read in all the public taverns and tea-houses. It is one of the most powerful engines of state; and a series of this paper would explain the nature of the government, better than all the moral maxims of antiquity on which it is supposed to be founded. Through it are all the measures of the government, or rather of the sovereign, communicated to the public. If he fasts or feasts, promotes or degrades, levies or remits taxes, feeds the hungry, clothes the naked, rewards virtue, or punishes vice, or, in short, whatever laud-

China. able action he may perform, it is announced in this state paper, with the motives and the reasons that may have given rise to it. Every sentence of death, with an abstract of the charges and the trial, every mitigation of punishment, are also published in this Gazette.

The grand leading principle of this patriarchal Government is to place the Sovereign at as great a distance from the people, and as far removed from mortality, as human invention could suggest. They not only stile him, the "Son of Heaven," but believe him to be of heavenly descent; and this superstitious notion appeared in a manner sufficiently remarkable, by the obstacles thrown in the way of the present Mantchoo dynasty, on account of their family not being able to trace their descent farther back than eight generations; a defect of ancient origin, which was considered by the Chinese as a great reproach. Kaung-hee, aware of their prejudices, caused the genealogy of the Tartar family to be published in the Gazette. It stated that "the daughter of heaven, descending on the borders of the lake Poulkouri, at the foot of the White Mountain, and eating some red-fruit that grows there, conceived, and bore a son, partaking of her nature, and endowed with wisdom, strength, and beauty; that the people chose him for their Sovereign, and that from him were descended the present 'Son of Heaven' who filled the throne of China." And this explanation wiped away the reproach, and fully satisfied the subjects of the "celestial Empire."

In the capacity of Sovereign, the Emperor of China is supposed to sustain two distinct characters. The first is that of a High Priest, in which he, and he alone, mediates and intercedes with heaven for all the sins and misdeeds of his people. In this character he only can officiate at solemn feasts, when heaven is to be propitiated by suitable oblations. He alone has the merit of all the prosperity that the empire enjoys; but he also affects to consider public calamity to be the consequence of some act committed, or some duty neglected by him. When, therefore, insurrections, famines, earthquakes, or inundations, afflict the people, he affects the deepest humility, appears in the meanest dress, strips the palace of its ornaments, and suspends all the Court amusements; but even in this state of humiliation, he is held up as the peculiar object of heaven's attention, whether it be to punish or to bless.

His second character as Sovereign of the Empire is that of "the father and mother of his people." In this character, it is supposed, that his subjects bear the same relation to him that he stands in towards *Tien* or heaven. His ministers or magistrates execute his will, and are supposed to be placed as agents between him and the people, in the same manner as heaven has its agents to regulate the divine decrees on earth; but all power, honour, offices, and emoluments, emanate from him alone, and are revocable at his pleasure. His prerogative is undefined and undivided, unrestrained by any written law, and checked only by ancient custom, stronger even than law. "Heaven," says Confucius, has not two sons, earth has not two kings, a family has not two masters, sovereign power has not

China. two directors—one God, one Emperor," not for China alone, but for all the earth, the rest of the Sovereigns being considered as his vassals. This doctrine was boldly avowed on the occasion of Lord Amherst's embassy, when the ceremony of prostration was demanded, not as a mere ceremony, but as the sign and seal of vassalage; and, on this ground, was, of course, resisted.

This self-created universal autocrat is not only the fountain of all honour in his wide dominions, but of all mercy. He is held up, on all occasions, as the mediator for his people, stepping in between the sentence of the law and the execution of it, and with a fatherly tenderness remitting a certain portion of the punishment which the law awards, and which the magistrate has no power to dispense with. If a magistrate instructs the people, it is in the name of the Emperor; if he flogs them for a misdemeanour, he remits a certain number of blows as the Emperor's grace; he orders his ministers to attend at all times to the complaints of the people; and that none may be denied access to the chief magistrate of the district, a gong or drum is suspended at the outer gate of his dwelling,—but woe be to him who ventures to sound it without substantial reason—the Emperor's grace would not save him from at least a dozen strokes of the bamboo. Navarette says that the judge's drum at Nankin is covered with the hide of an elephant, and the drum-stick, a huge piece of timber, slung by strong ropes from the roof of the house. This poor Jesuit had a ready credulity to receive all for truth which the Chinese told him.

The name of the sovereign, however, rarely appears but in an amiable light; the people hear of him only as distributing rewards, punishing oppression, relieving the distresses of the poor, opening the public magazines in times of scarcity, and remitting all taxes where the state of the treasury will afford it. Thus, it appears, that Kien-lung, having received a report from the Board of Revenue, that a balance remained in the treasury of seventy millions of ounces of silver, issued an edict, by which he exempted all his people from one year's taxes. This is all very good, and so is the whole theory of this arbitrary government, as delivered in the following rescript, which the minister of Timour-khan put into the hands of this sovereign; were but the practice conformable with it, we might call it truly Utopian.

1. Study with eager attention the will of heaven.
2. Be careful to tread in the steps of your ancestors, and to imitate their virtues.
3. Cease not to show your respect and gratitude to the august parents who gave you birth.
4. Watch over your people with a fatherly fondness.
5. In the exercise of sovereign power, preserve an upright heart, and an elevated soul.
6. Be moderate in your pleasures.
7. Drink little wine.
8. Do not lavish your treasures.
9. Extend your benefits to men of merit.
10. Make your justice formidable to criminals.
11. Drive from your presence knaves and flatterers.
12. Cherish upright and sincere men, and receive with temper their wise remonstrances.
13. Study the character of those you employ, and proportion their employments to their talents.
14. Regulate your time to your occupations, so that they may suit each

China. other. 15. Let not a day pass without studying the maxims of the ancients. And he concludes by observing that, by putting in practice these fifteen precepts, he would secure to himself a happy reign, and to his people prosperity and the blessings of peace.

In Kaung-lee's declaration on the appointment of his successor, a short time previous to his death, he observes, that "the true way for a sovereign to perform his essential duty towards heaven and the memory of his ancestors, is to procure for the people peace and plenty; to make his own happiness consist in the happiness of the people, and his own heart the heart of the whole state;" and he adds, "although, since I have occupied the throne, I cannot say that I have succeeded in changing the bad customs, and reforming the morals of my people; although I may not have been fortunate enough to give plenty to every family, or the necessaries of life to every individual, yet I may venture to assert, that, during my long reign, I have had no other view than to procure for the empire a solid peace, and to render all my people satisfied in their respective conditions. During my whole reign, I have caused the death of no one without a sufficient reason. I have never ventured upon any useless expence to be defrayed from the public treasury; it is the blood of the people. I have drawn nothing from it that was not necessary for the subsistence of the army, and for relieving the calamities of famine," &c. &c.

The ancient and established maxims of filial piety form, however, the grand basis of the Chinese government. Every son is supposed to hold the same relation to his father that the people do to the sovereign; and the same unnatural and unwarrantable power which is given to the father over his children could not consistently be withheld from the emperor. No wickedness or unnatural treatment can, on the part of the parent, relieve a son from his duties. The merit of every good action performed by the son is ascribed to the education given to him by the father, but the son bears his own disgrace. In like manner, the sovereign receives the whole merit of the country's prosperity, but his ministers incur the disgrace of all its misfortunes. To be consistent in thus placing the young and vigorous at the mercy of the old and feeble, the Emperor affects to pay the same homage and obedience to his mother, that are due from children towards their parents. The effect of this state morality, destructive of all real sentiment, is that of rendering every man a slave to some other, and establishing a system of tyranny, descending in an uninterrupted chain from the Emperor down to the meanest peasant. But this is not the worst; every man distrusts his neighbour; because every man is known to assume a character that does not belong to him, and constantly to act the hypocrite in public.

The jealousy and suspicion which prevails from the sovereign on the throne to the lowest of the magistrates, evince how little they trust to the fine maxims of morality, by which it is pretended the throne is supported, and the happiness of the people secured. No magistrate, for instance, can hold an employment in a district where he has relations: he cannot marry in that district; he cannot pur-

China.

chase lands in it; if his father or his mother should die, he must immediately resign his employment to fulfil the duties which a son owes to his parents, and which cease not with life; and, at all events, he is removed at the end of three years. No two relations within the fourth degree can sit together at the same board. In each of the six boards, which sit in Peking, there is a censor, who has no deliberative voice, but listens to their discussions, makes his remarks, and, like our speaker in the House of Commons, keeps them in order, refers to precedents, &c. He is supposed to be the confidential servant of the Sovereign, from whom he is informed of what is going on, and what are the sentiments of the several members. These six *Co-laos* may be considered as imperial spies, and they form an extraordinary board called *Tso-tche-yuen*, whose chief business is that of dispatching their visitors or sub-censors to all parts of the empire, to examine into and report upon the conduct of the several officers, and to discover whether any and what abuses are alleged against them; and, to complete the system of espionage, persons are invited to send up informations against the officers of government, all of which are registered in this extraordinary tribunal.

In this precarious situation, a magistrate may consider himself fortunate if he escapes the shafts of private malice, or retires from office without having incurred disgrace or some more serious punishment for the commission of some fault, or the dereliction of some duty; for, where the offices of state are open to the lowest of the people, when possessed of the requisite qualifications, the candidates for employment become so numerous, that every trifling fault is laid hold of to create a vacancy; and these frequent removals and degradations fall in precisely with the system of the government, which is to break down all connection between the officers and the people, and to turn the respect and veneration of the latter exclusively to the Sovereign. On the same principle, it is supposed that the extortions and malversations of officers high in the government are frequently winked at, until, at a proper season, the hand of power lays hold of the treasure corruptly obtained, and gets rid, in a legal manner, of the whole family of the delinquent. It is true, a magistrate in China is tried by his brother magistrates, but when the Sovereign is the accuser, as is generally the case where an officer of state is the accused, the result is pretty certain. The favourite and principal adviser of the late Kien-Lung was brought to trial by the present Emperor Kia-King on charges of the most frivolous nature, as that of having walked through the middle gate, which is alone reserved for the Emperor, having a pearl in his possession larger than any belonging to the imperial family, &c., but the object was answered; he was condemned to death, his whole property, which was immense, confiscated, all his relations dismissed from their employments, and banished into Tartary. We may form a tolerably correct opinion of the manner in which the criminal courts administer justice in cases wherein the Emperor is personally concerned, from the trials that took place in consequence of the recent attempt that was made to assassinate Kia King. He announces to the public a revolt, takes blame to him-

China.

self, abuses his ministers for their negligence, to which he ascribes his misfortune, and ends his proclamation in a strain of self-reproach, and great hypocritical humility. As the greater part of the handful of rebels who attempted to storm the palace were killed in the act, and the rest that were taken put to death, some by beheading, others by a slow and lingering process, some hacked and mutilated in the public market-place, and others "cut into ten thousand pieces," it might be supposed that here the business ended; no such thing. The Emperor, in his proclamation, denounces a particular sect which once caused a revolt in four provinces that took eight years to subdue; hence the country magistrates, to make amends for the carelessness of the ministers, persecuted all sects, and among others the Christians. One of the magistrates had the courage to send to the capital a spirited remonstrance, in which he stated that many innocent persons had been brought to trial, tortured, and suffered death; that numbers were unjustly confined, passed from court to court, after being put to the torture under pretence of preparation for trial, and that they were finally liberated, without trial, after their health was destroyed, and their property wasted. The whole document exhibits a melancholy picture of abuses in the administration of the criminal jurisprudence of this supposed virtuous and humane nation.

The administration of the government is conducted by six departments, to each of which there is a president and a certain number of members, forming so many boards similar to those of our Admiralty and Treasury Boards; and the six presidents form a distinct board of themselves, which, with certain Princes of the Blood may be called the extraordinary Council of the State. Each board sends out its appropriate officers to every part of the Empire, with and from whom it has to correspond, and receive reports, abstracts of which, and of all its proceedings, are daily laid before the Emperor by one of the *Collaos* or *Pescants*, whom he generally selects as his favourite and confidential minister and adviser. The respective duties of these boards are so interwoven with the laws of the Empire, that a brief view of the laws will best explain the nature of the executive governments. (*Grozier and Du Halde's Hist. of China.—Mém. sur les Chinois.—Macartney's Journal.—Staunton's Authentic Account of an Embassy, &c.—Barrow's Travels in China.*)

When Pauw observed that China was governed by Law the whip and the bamboo, he was not aware of the theoretical application of these instruments, especially the latter, to the whole code of civil and criminal law. The remark was not meant to extend beyond the practical application of these machines to the human body, which, it must be owned, are effectual aids towards the establishment of a strict police, and that they are freely enough administered in keeping the peace among the lower orders; but their use in this way is by no means so extensive as is generally supposed, and as the letter of the law would seem to imply. This great empire may, notwithstanding, be aptly enough compared to a great school, of which the magistrates are the masters, and the people the scholars. The bamboo is the ferula,

China.

and care is taken that the child shall not be spoiled by sparing the rod. The bamboo, however, is not used merely for flogging the people. In the fundamental laws of the empire, it forms the scale by which all punishments are supposed to be proportioned to the crimes committed, and which are carefully dealt out by weight and measure; and here also we recognise the work of an ancient people in a rude state of society. In a small family, or a community consisting of a certain number of families, it may just be possible to "adapt the penalties of the laws in a just proportion to the crimes against which they are denounced;" but the continuance of such a system in an overgrown commonwealth affords no proof of refined or extensive notions of jurisprudence. Punishment, as an example to deter others from the commission of crimes, would seem indeed to be less the object of Chinese legislation, than that of satisfying the claims of rigid justice; to wipe off a certain degree of crime by the infliction of a proportionate degree of suffering.

The code of laws called the *Leu-lee* has undergone several changes by different dynasties, but the principle of the laws has remained the same. This book is to China what "Burns's Justice" is in England, and is familiar to all who have any pretensions to literature. "The magistrates and the people," says the Emperor Sun-chee, "look up with awe and submission to the justice of these institutions." An European will regard them with different feelings. The frequency and the severity of corporal punishments, if literally inflicted, would be shocking and disgusting; but, as Sir G. Staunton has observed, "there are so many grounds of mitigation, so many exceptions in favour of particular classes, and in consideration of peculiar circumstances, that the penal system, in fact, almost entirely abandons that part of its outward and apparent character." The same observation will apply to the penalty of death, which appears to be affixed to crimes whose enormity are not such as would be deemed worthy of this extreme of punishment in the most sanguinary code of Europe; for if we are to judge from the very small comparative number of criminals that are annually executed, one of two conclusions must necessarily be drawn, either that capital offences are very rare, or that the laws are very lenient. Pere Amiot says, that, in 1784, the list of criminals under sentence of death, and ratified by the emperor, amounted to 1348 persons, which, he observes, was considered to be unusually great. It is about one in 108,000, at which rate not more than 160 would suffer annually in the whole population of Great Britain and Ireland.

The number of blows to be inflicted with the bamboo may not only be considered as the measure or scale of crimes, but as regulating also the mode or practice of punishment. The letter of the law, severe as it may appear to be in denunciation, is more lenient in execution. Thus, ten blows of nominal punishment are practically reduced to four, and 100 to 40; and, in many cases, these blows are redeemable by fine.

This bamboo, that makes so conspicuous a figure in the Chinese code, is limited by law to two sizes; the larger 5 feet 8 inches in length, 2½ inches broad,

and 2 inches thick, weighing 2½ pounds; the smaller the same length, 2 inches broad, and 1½ thick, weight about 1½ pound.

The *cangue*, or more properly the *kia*, is a wooden collar for the neck, 8 feet long, 2 feet 9 inches broad, weighing in ordinary cases 33 pounds.

The iron chain, by which all criminals are confined, is 7 feet long, weighing 6½ pounds; besides which they use wooden handcuffs and iron fetters.

Various kinds of torture of the hands, feet, ankles, &c. are made use of to extort evidence or confession; but it is not permitted to put the question by torture to those who belong to any of the eight privileged classes, in consideration of the respect due to their character; nor to those who have attained their 70th year, in consideration of their advanced age; nor to those who have not exceeded their 15th year, out of indulgence to their tender youth; nor, lastly, to those who labour under any permanent disease or infirmity, out of commiseration for their situation and sufferings. The eight privileged orders spring out of, 1. Imperial blood and connexions. 2. Long service. 3. Illustrious actions. 4. Extraordinary wisdom. 5. Great abilities. 6. Zeal and assiduity. 7. Nobility of the first, second, and third rank. 8. Birth—all of which, excepting the first, seventh, and eighth, have not, in fact, any existence. Their chief privilege consists in not being liable to be tried for any offence without a specification of the crime being laid before the emperor, and his express commands issued for that purpose.

There are five degrees of punishment.

The first degree is a moderate correction inflicted with the lesser bamboo, "in order that the transgressor of the law may entertain a sense of shame for his past, and receive a salutary admonition with respect to his future conduct." This correction extends from ten to fifty blows; the first, in practice, reduced to four by the emperor's grace; the last never exceeds twenty blows.

The second class of punishments extends from sixty to a hundred blows, of which from twenty to forty are actually inflicted.

The third division is that of temporary banishment to any distance not exceeding 500 *lee* (about 150 miles), "with the view of affording opportunities of repentance and amendment," and it extends from one to three years' banishment.

The fourth degree of punishment is that of perpetual banishment, which is reserved for the more considerable offences, and extends to the distance of 2000 and even 3000 *lee*, with 100 blows of the bamboo.

The fifth and ultimate punishment which the laws ordain, is death, either by strangulation or decollation.

At the head of the code are placed ten offences of a treasonable nature. 1. *Rebellion*, defined an attempt to violate the divine order of things on earth. 2. *Disloyalty*, an attempt to destroy the imperial palaces, temples, or tombs. 3. *Desertion* to a foreign power. 4. *Paricide*, or the murder of parents, uncle, aunt, grandfather, or grandmother. 5. *Massacre*, or the murder of three or more persons in one family. 6. *Sacrilege*, or stealing from the temples any sacred article, or anything in the immediate use of

China.

China.

the sovereign. 7. *Impiety*, or negligence, and disrespect of parents. 8. *Discord in families*, or a breach of the legal or natural ties, founded on connections by blood or marriage. 9. *Insurrection* against the magistrates. 10. *Incest*, or cohabitation of persons related in any of the degrees to which marriage is prohibited. And these crimes are stated to be placed at the head of the code, from their being of so heinous a kind, that, when the offence is capital, it is exempted from the benefit of any act of general pardon, and that the people may learn to dread and avoid them.

Offences committed by officers of government, which, in ordinary cases, are punishable by the bamboo, are commutable for fine or degradation, according to the number of blows to which they are nominally liable. Thus, if publicly offending, instead of 60 blows, they forfeit a year's salary; and, instead of a hundred, lose four degrees of rank, and are removed from their situation. If the offence be of a private nature, the punishment is doubled. The only male descendant of parents or grandparents, who are aged and infirm men, whose age exceeds 70, and youths under 16, are entitled to the indulgence of commuting the punishment awarded by law. Women too may have the sentence of banishment remitted on payment of a fine; and, when convicted of offences punishable with the bamboo, "they are permitted to retain a single upper garment while the punishment is inflicted, except in cases of adultery, when they shall be allowed the lower garment only."

The following table exhibits a scale of pecuniary redemption, in cases not legally excluded from the benefit of general acts of grace and pardon. They are not necessarily redeemable; but, by edict of *Kien Lung*, may be made so upon petition.

Rank of the party offending.	Sentence.	Pecuniary Commutation.
		<i>Oz of Sil.</i>
An officer above the 4th rank	Death by strangulation or decollation.	12,000
— of the 4th rank		5,000
— of the 5th or 6th rank		4,000
— of the 7th, or any inferior rank, or a doctor of literature		2,500
A graduate or licenciate		2,000
A private individual		1,200
An officer above the 4th rank	Perpetual banishment.	7,200
— of the 4th rank		3,000
— of the 5th or 6th rank		2,400
— of the 7th, or any inferior rank, or a doctor of literature		1,500
A graduate or licenciate		1,200
A private individual		720
An officer above the 4th rank	Temporary banishment, or blows with the bamboo.	4,800
— of the 4th rank		2,000
— of the 5th or 6th rank		1,600
— of the 7th or any inferior rank, or a doctor of literature		1,000
A graduate or licenciate		800
A private individual		480

China.

There is every reason to believe that these pecuniary commutations of banishments bring considerable sums into the treasury.

The *Ta-tsing-leu-lee* embraces an epitome of the whole system of government, and of civil and criminal jurisprudence. Besides the introductory part, which contains a general view of the laws, the code consists of six principal divisions, corresponding with the six supreme boards or departments, by which the general administration of the empire is conducted. Thus, the first division of the code relates to that part of the civil law, which falls under the cognizance of the *Lee-pou*, or the department which examines candidates for employment, and nominates to appointments, subject to the approbation of the emperor. This division consists of two chapters, the first defining the duties, and regulating the offices, of the several magistrates, the rule of hereditary succession, and the penalties attached to malversation. The second book relates chiefly to the conduct of the provincial magistrates. The capital offences classed under this division are, great officers of state presuming to confer appointments on their own authority, and without the sanction of the emperor; undue solicitation of hereditary honours; all cabals and state intrigues among the officers of government; collusion between the provincial magistrates and the officers of the court; addressing the emperor in favour of any great officer of state, which is construed into a treasonable combination, subversive of legitimate government; destroying edicts or seals of office, all of which, however, fall within the class of redeemable punishments, which are not excluded from any general act of grace or pardon.

The second division of the code relates to the *Fiscal Laws*, which are placed under the cognizance of the *Hoo-pou*, or financial department. They are very various, and relate—1. To the enrolment of the people; personal service; levying of taxes; punishment of persons deserting their families; care of the aged and infirm. 2. The law of holding, mortgaging, selling, &c. lands and tenements. 3. Regulations respecting marriages and divorces. 4. Respecting public property, the coinage, the revenue, the public stores. 5. Duties and customs; smuggling; false manifests, &c. 6. Private property; the law of usury; of trusts, &c. 7. The regulations concerning sales and markets; monopolizing and fraudulent traders; false weights, measures, and scales; manufactures not conformable to the fixed standard, &c. The section concerning marriages and divorces is brought under this division of the code, for no other reason, it would seem, than to regulate the descent and distribution of property. The law allows seven justifiable causes of divorce. 1. Barrenness; 2. lasciviousness; 3. neglect of her husband's parents; 4. talkativeness; 5. thievish propensities; 6. envious and jealous temper; 7. inveterate infirmity. But, in spite of any or all of these causes, a wife cannot be divorced, if she can plead any of the three cases; 1. having mourned three years for her husband's parents; 2. her husband having become rich since the time of marriage; 3. the wife having no parents living to receive her.

The *Lee-pou*, or board of rites and ceremonies, takes cognizance of all offences committed under the third division of the code, which is subdivided into two

China.

sections; and relate, 1. To the *sacred rites*; the administration of the prescribed ritual; the care of altars, sacred terraces, and the tombs; unlicensed forms of worship; magicians; leaders of sects; and teachers of false doctrines. 2. To miscellaneous observances respecting the palaces, the Emperor, his equipage, and furniture; to the public festivals and days of ceremony; sumptuary laws, relative to dress and habitations; celestial observations and appearances; regulations for funerals and country festivals.

The *fourth division* contains the laws by which the military are governed, the direction and superintendence of which are placed under the department of state called the *ping-pou*. It consists of five sections. The first relates to the protection of the palace, and of course to the person of the Emperor; the duties of the imperial guards; examination of passports, &c. The second is entitled the *government of the army*, and may be considered as the mutiny act, or articles of war, of China. Every neglect of duty, disobedience of orders, and want of discipline; fraud, embezzlement, desertion, are punished with extreme severity, and many of the offences herein specified are capital. The third section relates to the *protection of the frontier*, a most important consideration with this suspicious government. The fourth prescribes regulations respecting the horses and cattle belonging to the army. The fifth for the expressmen and government posts, the post-horses, messengers, and horses, employed in the conveyance of dispatches.

The *fifth division* contains the Code of Criminal Law, administered by the *Hing pou*, or criminal tribunal, which supplies the judges or assessors to all the other departments. It consists of eleven sections. The first, entitled *robbery and theft*, awards punishments for every species of robbery or theft that could well be devised; extorting property by threats; obtaining it under false pretences; kidnapping and selling free persons as slaves; disturbing graves, &c. The second relates to *homicide*, and may be considered as a most singular, if not successful, attempt to discriminate the exact proportion of guilt, for the same offence, in different persons, or different degrees of offence in the same person, according to the situation and circumstances of the offending parties. In every case of preconcerted homicide, the original contriver is condemned to die by decapitation; the accessories by strangulation; accessories to the intention, but not to the fact, are punishable with one hundred blows, and perpetual banishment. Those who murder, with intent to rob, are beheaded, without distinction between principals and accessories. Parricide subjects all parties to suffer death by a slow and painful execution; the attempt to commit parricide is death by decapitation. Slaves attempting to murder, or actually murdering their masters, are liable to the same punishment. A husband may kill his wife, if caught in the act of adultery, and also her paramour; and a thief may be put to death, if taken in the act of robbing a house; but, in either case, it would be murder, if put to death after being seized. The preparing of poisons, or rearing of venomous animals, are capital offences. Practitioners of physic, or barbers (for they have no sur-

geons), who or perform rules are given; but, if proved to have been in judgment, the offence is redeemable; but, if the medicines were given intentionally to kill or injure the patient, the practitioner must suffer death by decapitation. All persons guilty of killing in an affray, though without any express or implied design to kill, whether the blow be given with the hand or the foot, with a metal weapon or instrument of any kind, shall suffer death by strangulation. There is a clause, however, by which all persons killing another in play, by error, or purely by accident, may be permitted to redeem themselves from the punishment of killing or wounding in an affray, by the payment of a fine to the family of the deceased person; but the case of *pure accident* is very carefully defined and exemplified. It must be one "of which no sufficient previous warning could be given, either directly, by the perception of sight and hearing, or indirectly, by the inferences drawn from judgment and reflection."

In the third section, entitled "Quarrelling and Fighting," there is a minute and circumstantial detail of blows given under every conceivable case and situation, and in every possible relation in which the parties could stand towards each other. It fixes the periods of responsibility for the consequences of a wound; it awards the penalty of death on a slave who shall strike his master; on a son who shall strike his father or mother; on a grandson who shall strike his paternal grandfather or grandmother; on a wife who shall strike her husband's father, mother, paternal grandfather or grandmother; but, if a father, mother, paternal grandfather, or grandmother, shall chastise a disobedient child or grandchild in a severe and uncouth manner, so that he or she dies, the party so offending shall be punished only with one hundred blows, which, in reality, are no more than forty; and, when any of the aforesaid relations are guilty of killing such disobedient child or grandchild designedly, the punishment shall be extended to sixty blows, and one year's banishment. A parent may, at any time, sell his children, with the exception only to strolling players, and professors of the magic art. This distinction which the law makes between the parent and child, and the almost unlimited authority which is given to the former over the latter, would lead one to conclude, that, if the crime of infanticide be not sanctioned, it is at least connived at, by the government. There is every reason, however, to believe that the extent of it has been grossly exaggerated, and that the greater part of infants taken up in the streets of large cities by the police have died in the birth, and been laid out, to avoid the expence of burial; or been exposed alive, with the view of their being taken care of as adopted children, or conveyed to hospitals for the reception of deserted children.

In the cases above stated, the child murdered is supposed to have been *disobedient*, which is a crime of the deepest dye, as affecting the principle on which the whole system of government is founded;

China.

with the needle, giving drugs, as contrary to the established and thereby killing the patient, but, if proved to have been in judgment, the offence is redeemable; but, if the medicines were given intentionally to kill or injure the patient, the practitioner must suffer death by decapitation. All persons guilty of killing in an affray, though without any express or implied design to kill, whether the blow be given with the hand or the foot, with a metal weapon or instrument of any kind, shall suffer death by strangulation. There is a clause, however, by which all persons killing another in play, by error, or purely by accident, may be permitted to redeem themselves from the punishment of killing or wounding in an affray, by the payment of a fine to the family of the deceased person; but the case of *pure accident* is very carefully defined and exemplified. It must be one "of which no sufficient previous warning could be given, either directly, by the perception of sight and hearing, or indirectly, by the inferences drawn from judgment and reflection."

In the cases above stated, the child murdered is supposed to have been *disobedient*, which is a crime of the deepest dye, as affecting the principle on which the whole system of government is founded;

China.

but from section 294, it is evident, that killing a son, grandson, or slave, under any circumstances, with the aggravation of imputing his death to an innocent person, is not a capital offence. "Whoever is guilty of killing his son, his grandson, or his slave, and attributing the crime to another person, shall be punished with seventy blows, and one and a half year's banishment." But "a child or grandchild who is guilty of addressing abusive language to his father or mother, paternal grandfather or grandmother; a wife who is guilty of addressing abusive language to her husband's father or mother, paternal grandfather or grandmother, shall, in every case, suffer death, by being strangled." They must, however, themselves complain, and themselves have heard the abusive language. In like manner, a slave is liable to capital punishment for addressing abusive language to his master.

The fifth book relates to Indictments and Informations of all kinds; the sixth to cases of Bribery and Corruption, and seems to contain provisions against bribery in almost every shape which it can be supposed to assume. It is not easy, however, to reconcile these apparent appropriate provisions with that systematic corruption which, under the less odious name of presents, is prevalent in every department of the administration of public affairs and public justice in China. There is a scale of punishment for the value of the bribe received, from one ounce of silver to 120 and upwards; the first entailing sixty blows, the last death, by strangulation, when the object is in itself lawful; but, if unlawful, an ounce of silver incurs seventy blows; and eighty ounces and upwards death, by strangulation. That they all take bribes is well known, yet it appears by a note in the original (*Leu-lee*), that, in the 33d year of Kien-lung, a governor of a city in the province of the capital was tried, and sentenced to suffer death, for taking a bribe of 7000 ounces of silver to stop proceedings in a case of disorderly conduct, and contempt of court; though, finding himself unable to accomplish the object, he had returned the money. In like manner, there are so many provisions against extortions, and corrupt practices on the part of great officers of state and their families, that it might be supposed no such practices could exist. The last section of this book is curious, as affording a proof of the care with which the imperial prerogative is fenced round. "All military officers of government, whether stationed at Court or in the provinces, are prohibited from receiving presents of gold, silver, silk-stuffs, cloths, wages, or board-wages, from individuals in any of the three principal ranks of hereditary nobility" (mostly related to the royal family and other Tartar chieftains). Any breach of this law deprives them of their rank and employment, and renders them, moreover, liable to the punishment of one hundred blows, and remote perpetual banishment. The second offence of this kind is capital.

The seventh book awards punishment for frauds and forgeries, falsification of the imperial seal or imperial almanac, counterfeiting the current coin of the realm, seducing persons to transgress the laws, &c. The eighth is entitled Incest and Adultery.

China.

Criminal intercourse with an unmarried woman, though by mutual consent, is punishable with seventy blows; with a married woman, eighty blows; deliberate seduction with either, with one hundred blows; a rape with death, by strangulation; and criminal intercourse with a girl under twelve years of age is punishable as a rape. Adultery with the wife of any civil or military officer is death; but civil or military officers committing adultery with the wife of a private individual is degradation, one hundred blows, and wearing the cangue for a month. In all ordinary cases of adultery among the people, the punishment is one hundred blows, and the cangue for a month. An unnatural crime forcibly committed, or committed on boys, is punishable as a rape, but by mutual consent the parties are punishable only with one hundred blows, and the cangue for a month. In cases of criminal intercourse, the law is more severe towards the woman than the man, and towards slaves than freemen. "All civil or military officers of government, and the sons of those who possess hereditary rank, who shall frequent the company of prostitutes and actresses, shall be punished with sixty blows," which is, in fact, no punishment at all, as the blows, in reality, are reduced to twenty, and redeemable for a mere nominal sum, not exceeding two or three shillings.

The ninth book is entitled Miscellaneous Offences, among which is that of gaming; any person convicted of which is punishable with eighty blows. Yet in every street and corner, and in the very temples, the lowest of the people may be seen daily, and every hour of the day, playing at cards, dice, or a sort of game resembling chess. Accidental incendiaries are flogged, and fined, according to the consequences of the fire they have occasioned, and wilful incendiaries are punished with death, provided it be proved that the fire was occasioned with a view of plunder. Stage-players and musicians are prohibited from representing emperors, empresses, famous princes, ministers, and generals of former ages, on pain of receiving one hundred blows for every breach of this law. Yet, as these are the favourite and most usual exhibitions, it may be presumed that this law is obsolete; there is, indeed, a saving clause which says, "that, by this law, it is not intended to prohibit the exhibition on the stage of fictitious characters of just and upright men, of chaste wives, and pious and obedient children; all which may tend to dispose the minds of the spectators to the practice of virtue."

The tenth and eleventh sections contain regulations with regard to arrests and escapes, imprisonment, judgment, and execution.

The sixth and last division contains the laws and regulations respecting the public works, which are placed under the superintendence of the department of state, called the *Cong-poo*, or board of public works. It has only two sections; the first relating to public buildings, the second to the public roads. From the first it appears, that this board has also the superintendence of the public manufactures of the state, such as military weapons, silks, stuffs, porcelain, &c.; and that, if any private individual be convicted of manufacturing for sale silks, satins, gauzes,

China. or other stuffs of this nature, according to the prohibited pattern of the *lung* (dragon), or the *lung-whang* (phoenix), he shall incur the penalty of one hundred blows, and the goods so manufactured be forfeited to the state. This book and the next, concerning the keeping in repair of the public roads, embankments, and bridges, contain a number of regulations and petty penalties for neglect and malversation, that are beneath the dignity of legislation, and fitted rather for the subjects of deliberation in a parish vestry. Indeed, the whole body of Chinese law, civil and criminal, consists of such minute meddling with all the common concerns of life, as to be utterly unfit for any practical application, except to such mere machines as the Chinese are, for whom it seems to be admirably suited to answer the intended purpose. Nothing can more clearly exhibit this great multitude of human beings as an inert and sluggish mass, without a heart, and without one single idea of the liberty and independence of the human mind, than the minute and paltry regulations under which it has voluntarily submitted to be bound and shackled for so many thousand years.

After all, there is reason to suspect that this minute measuring out of punishments by a scale, in order to adapt them to their respective degrees of criminality, is pregnant with the most gross injustice; and that, where so much pains are ostentatiously displayed to deal out justice by weight and measure, there is so much less of it in the execution. Many examples might be cited in confirmation of this opinion, but a few will suffice. In the eleventh volume of the *Chinese Memoirs*, Pere Amiot gives a curious account of a master mason that died by an accidental blow of the bamboo, while under a flogging by order of an officer of the household of a prince of the blood, whose house he was rebuilding in Peking. As culpable homicide is death by the law of China, the officer bribed one of the mason's labourers, for ten ounces of silver, and the promise of a respite, to take the blame on himself, as the consequence of a quarrel; and, for three ounces of silver, two or three of the labourers were to give evidence to that effect. The man was tried, and condemned to suffer death on the day of general execution in autumn. On the morning of that day, or the evening preceding, it is the custom, it seems, to bring up all the prisoners under sentence of death to be interrogated by the Colloas, or principal ministers of the crown; and, on this occasion, the heart of the bricklayer's labourer failing him, he discovered the whole transaction. The offending officer was immediately tried; and, coupling his original offence with the aggravated one of exposing an innocent person to suffer death, was sentenced to die by a slow and painful execution. Nor was this all; the judges and assessors of the court, who had originally tried the offence, were each degraded one rank, and mulcted of their salary and emoluments. This is given by Pere Amiot as an instance of Chinese justice; but it tells as strongly the other way, as if such gross iniquity, committed in open day, and in the presence of a multitude, and thus condoned at the very fountain-head, what may not be expected at a distance, where the stream is still more muddy?

China. That government can have no high notions of justice or morality, which punks at, and sometimes encourages, a crime, and finds a substitute, even when the punishment is death. Many of the servants of the East India Company can testify, from their own personal knowledge, to the truth of the severe remark of Pausanias, *Le juge veut faire une execution, et il lui faut un patient; or il prend celui qui se presente*. In the recent case of an English seaman being tried for the murder of a Chinese, when they failed in their endeavours to procure a black slave, or a criminal of Macao, or a sick person on the point of death, to execute,—not to satisfy justice, for it was an accidental death in a scuffle,—but to satisfy the criminal court of Peking, to whom they had unluckily for themselves appealed; they had recourse to one of the meanest and most paltry expedients that ever disgraced a civilized government. All the proceedings, says Sir G. Staunton, “were founded on a story fabricated for the purpose; a story in which the Europeans did not concur, though asserted to have done so; which, in fact, the Chinese magistrates themselves, or the merchants under their influence, invented; which the Chinese witnesses, knowing to be false, adopted; and which, lastly, the sovereign himself, appears to have acquiesced in, without examination.” Under such a government, the laws are either a dead letter, or may be so perverted, that, under their sanction, the innocent may be made to suffer, and the guilty escape punishment.

In addition to all this, that horrible system of visiting the crimes of the guilty upon the heads of the innocent, which pervades all the despotic governments of the East, is also practised in China, in all cases of rebellion and treason; though it is not carried so far as among the Hindoos, who, not content with cutting off a whole family, swept away whole towns and villages in which treason had appeared, as a terrible example to prevent other villages from harbouring traitors. Such are the dreadful effects of despotism, and the miseries inflicted on innocent families, where the people have no voice in the government;—such a government is always more ready to punish than to protect. (*Ta-tsing-leu-lee*, translated by Sir G. Staunton.)

The condemned criminals for ordinary offences ^{Prisons.} are kept in prison till autumn, when they are all executed in every part of the Empire on a particular day. In general, the prisons are described as spacious, neat, and clean. Navarette, who was himself confined in one of them, says, that they have large airy courts for the prisoners in the day-time; that overseers are always present to quell any noise or disturbance, and that they contain temples for the priests to resort to. The priests, he says, make a harvest in the prisons, as those whose trials were pending were constantly consulting the priests as to the issue, and they became the more religious, the nearer the day of trial approached. Criminals are kept in chains, and always apart; so are the women kept separate from the men; and the missionary observed so little gallantry on the part of the men, that though there were gratings in the doors of the women's cells, the Chinese never once visited them. A very different picture, however, is given of the

China.

state of the prisons, and the prostitution of the females confined in them, in the province of Canton, from better authority than Navarette,—an official report to the Emperor on the state of the prisons. The scenes of depravity therein exhibited are horrible beyond description. (*M.S. Report.*)

The durability of a system so arbitrary, and an administration so corrupt, is not a little owing to the incessant and indefatigable vigilance of the police; to the absence of all political meetings or societies, and of all discussions respecting public measures; to the gradation of obedience throughout every class of society, inculcated by precept, by example, and by the bamboo; and certainly not a little to that spirit of national industry, which is the grand preserver of national tranquillity.

Revenue.

It is utterly impossible, from any document that has appeared of an authentic nature, to form any estimation of the amount and value of the revenue. From an extract of the *Y-tung-tche* (Encyclopædia), translated by Mr Morrison, it appears, that the annual value of the imports amounts to about 86,000,000 leang (of 6s. 8d. each), or L. 12,000,000 Sterling; but whether this is exclusive of the taxes paid in kind to the public granaries and magazines, or whether these are included in that sum, it is not stated; but as the value of money is only about one-fourth part of its value in England, fifty millions of money, in an economical government like this, where the officers and magistrates are so shamefully paid that they could not live without robbing the people, may be considered as an ample revenue for all the necessities of the state. The largest sum arises from an impost of about one-tenth on the estimated produce of the land; a duty on salt yields about one-fourth of the land-tax; and the customs and minor taxes make up a sum altogether about equal to that of the salt-tax. Besides, grain, silks, cottons, and various manufactures, are paid in kind into the imperial magazines, and are distributed as clothing to the troops, and in part payment to the magistrates, and also as presents to those distinguished by imperial favour, and to foreign ambassadors. A forced loan, never to be repaid, and a capitation tax, the most unjust of all taxes, because the most unequal, are the odious resources to which the Chinese government is occasionally compelled to have recourse. The immense treasures supposed to have been amassed in Tartary by the reigning dynasty, exist only in the imagination of the Chinese.

Religion.

Religion, as a system of divine worship, as piety towards God, and as holding forth future rewards and punishments, can hardly be said to exist among the people. It is here, at least, neither a bond of union, nor a source of dissension. They have no sabbatical institution, no congregational worship; no external forms of devotion, of petition, or thanksgiving, to the Supreme Being; the Emperor,—and he alone, being high priest, and the only individual who stands between Heaven and the people, having the same relation to the former that the latter are supposed to bear to him,—performs the sacred duties, according to the ancient ritual, and at certain fixed periods; but the people have no concern with them. The Emperor alone officiates at all the so-

China.

lemn ceremonies, for propitiating Heaven, or expressing a grateful sense of its benefits; and as "Sacrifices and oblations can only be acceptable to heaven, when offered up with humble reverence, and a pure and upright heart," he prepares himself for such occasions by fasting and abstinence, and acts of benevolence and mercy to his subjects.

The equinoxes are the periods when the grand sacrifices in the temple dedicated to Heaven, within the precincts of the palace, are offered up; when every kind of business in the capital, all feasts, amusements, marriages, funerals, must be suspended during the ceremony, the moment of which is announced to the people by the tolling of the great bell in Pekin.

A ridiculous dispute was carried on with great vehemence between the Jesuits and other sectaries of the Catholic religion, whether the Emperor did not offer his sacrifices and oblations to *Tien* as the visible and material heaven, and whether the Chinese were not atheists, at the head of whom he was the officiating high priest. There is not an expression in their ancient book of rites that warrants such a supposition. The *Lee-Kee* describes the *Tien* as having neither voice, nor smell, nor figure, substance, nor dimensions; it gives him the attributes of omnipotence, omniscience, and ubiquity, and considers him as rewarding the good, and punishing the bad; that public calamities are the instruments he employs to excite in the sovereign, and through him in the people, a reformation of morals. The names by which the sovereign power is known in their writings is *Whang-tien*, the illustrious heaven; *Chang-tee*, the Supreme Ruler; *Tien-tee*, heaven and earth; *Che-chung*, the first and the last (Alpha and Omega); *Ken-puen*, root and branch. When the Jesuits asked the Emperor Kaung-hee, whether the sacrifices were made to the Sovereign Lord of Heaven, the author and preserver of all things; whether the ceremonies in the hall dedicated to Confucius, were in honour of his memory as a benefactor to his country; and whether the rites observed towards ancestors in the hall dedicated to them, were merely to show respect and gratitude?—Kaung-hee replied, that they comprehended very well the Chinese religion; but the prayer of *Kaung-hee*, before going into battle, and published in the *Pekin Gazette*, might have satisfied the most scrupulous. "Sovereign Lord of Heaven, the Supreme Ruler, receive my homage, and grant protection to the humblest of thy subjects. With respectful confidence, I invoke thy aid in a war which I am compelled to wage. Thou hast heaped on me thy favours, and hast distinguished me by thy special protection. A people without number acknowledges my power. I adore in silent devotion thy manifold kindnesses, but know not how to manifest the gratitude which I feel. The desire of my heart is to give to my people, and to let strangers enjoy, the blessings of peace; but the enemy has put an end to this my most cherished hope. Prostrate before thee, I implore thy succour, and, in making this humble oblation, I am animated with the hope of obtaining thy signal favour. My only wish is to procure a lasting peace throughout the immense region over which thou hast set me."

China. (*Hist. Gen. de la Chine*, Tom. II.) The inscription over the doors of the Jesuits' church in Pekin, "To the only true God," &c. written with *Kaung-hee's* own hand, affords farther proof of his sentiments respecting the Deity.

All this, however, from the Emperor downwards, is full of absurd superstitions. The imagination of untutored man, not easily comprehending a power so almighty and universal, created a number of inferior spiritual beings as the harbingers and agents of his will; and these spiritual agents, which the Chinese call *Quei-shin*, are invisible attenuated beings, some white and good, the advocates of men, others black and wicked, the punishers of sin; and these "illustrious subjects of the Great Ruler," are supposed to preside over the five seasons of the year,—over mountains and rivers,—over the hearth and the door of the house,—and influence all the concerns of men. To these spirits certain duties are prescribed, and certain oblations offered; the men usually bring wine, the women tea; but these are private ceremonies and heartless duties; the devotion of religion was totally wanting; and in such a state it was not surprising that the doctrines and the practices of the sects of Tao-tse and of Fo should captivate the vulgar, and seduce them to a religion that spoke more strongly to the senses. It would seem, indeed, that the establishment of some popular religion is unavoidable, and that of Fo may, on this ground, be encouraged by the government, though it derives little or no support from it. The ancient religion of China entertained the idea of spiritual beings, but they never clothed them in a corporeal form. In the time of Confucius their temples were without images: their guardian gods and their evil genii were mere imaginary beings, to which they neither gave form or substance; but when the priests of Fo found their entrance into China, they brought with them all the follies and absurdities of the doctrine of Boudh, and grafted them on the superstitions of the Chinese. They filled their temples with all manner of images, each having its peculiar virtues and peculiar influences, and levying for each a tax on the credulity of the people. In some of these temples are not fewer than 300 sainted personages,—monstrous figures as large, and frequently many times larger, than human beings. Their bells and their beads, and burning of incense and tapers,—their images and their altars,—their singing and processions, were well calculated to seduce the populace, who had no outward forms of any religion. So strong was the resemblance of the interior of a temple of Fo,—the dress of the priests,—and the ceremonies of devotion, to those of the church of Rome, that one of the Catholic missionaries says, it seemed as if the devil had run a race with the Jesuits to China, and, having got the start of them, had contrived these things for their mortification.

The Tao-tse are of Chinese origin, and sprung up under the very nose of Confucius, 1500 years nearly before Christ. Their tenets resemble those of Epicurus; they pretend to magic and alchemy,—to consult oracles,—to deal with demons,—and keep old women, who are regarded as a kind of witches. The priests of Fo came from upper India into China,

China. by invitation from a weak emperor, between the 60th and 70th year of the Christian era. Their tenets resemble the Pythagorean. They kill no living animal,—eat no animal food, lest they might partake of a relation or friend, whose soul had taken up its abode in the animal; they believe that the human soul, in its transmigration through an infinity of corporeal existences, becomes purified and perfect, and at length is reunited to the Deity, from whom it originally emanated. They consider the consummation of felicity to consist in the annihilation or total suspension of every faculty of the soul, leaving a void for that of Fo to occupy. Arrived at this stage, the devotee soon dies from exhaustion and want of food; his body is burnt, the ashes put into eight urns,—a tower of nine roofs and eight apartments is built, and an urn placed in each apartment; this is said to have been the origin of the numerous tall pagodas that appear in every part of China. It is pure Shamanism, which may be traced from the Caspian Sea to Japan; from the Saghalien Oula to the Persian Gulf. The priests profess, and many of them are said to practise, the most refined piety,—the most sublime notions of virtue; prayers, fastings, austere and rigorous punishments for the sins of others; chastity, abstinence, penitence, contempt of bodily suffering, to secure for the indestructible soul a better abode in the circle of its transmigrations.

Some of the Catholic missionaries, however, have represented the priests of Fo as living in all manner of vice and luxury; but the testimony of unprejudiced travellers is against them, and even several of the Jesuits speak highly in their favour, saying that, in their moral doctrines, there is little to reprehend; that they inculcate benevolence, humility, reciprocal kindness, command over the passions, and tenderness towards the brute part of the creation. But it may be questioned, whether the priests of Fo or Tao-tse act on any fixed principles. Some of them, for instance, refuse to drink wine, others to eat garlic and onions; some practise celibacy, and profess perpetual continence; others have several wives and concubines. It is quite certain that neither of them are much respected by the government. Their protection or persecution depends on the caprice or feeling of the ruling sovereign. At one time we find their temples demolished, the materials employed for the public buildings,—the bells and brazen statues melted down into money,—and the priest, by an imperial edict, reduced to the rank of the people. One emperor persecutes the Ho-chang of Fo and encourages the Tao-tse; he drinks the beverage of immortality, and dies soon after; his successor eradicates the Tao-tse for poisoning the sovereign, and sanctions the worship of Fo. At present the number of temples dedicated to Fo, and of the priests attached to them, is incalculable. They not only occur in every city, town, and village, but are erected, on a small scale, in private houses, in which priests are employed, though not generally, to instruct the children of the family. One emperor observed, that there were not fewer than 100,000 priests of Fo, and as many priestesses; and that the wisest policy would be to make them marry and get

China.

children for the good of the state; that a religion, which imposed restraint on the natural passions given to man, was undeserving of any regard. No temple can be built without special permission; and they are always used for state purposes by the officers of government, for foreign ambassadors, &c. in their journeying through the country.

The Christian missionaries are exposed to the same capricious conduct; caressed at one time, persecuted at another. One emperor gives them money towards building churches, and the same emperor converts them into public granaries and public schools. In the year 1747, five missionaries were beheaded in Fokien, and two Jesuits strangled in the same year in Kiang-nan; all of which was done according to the law, which says, that the chief of any sect who seduces the people from their duties, under religious pretences, shall be strangled.

The people are ready enough to embrace any of these religions, but the emperor and his court, and all the officers and magistrates, adhere to the ancient religion, as laid down by Confucius, though there is an obvious leaning of the present Tartar dynasty towards that of Fo or Budh, which is that of the Lamas of Thibet. The great temple at Gehol, the summer residence of the Tartar sovereigns now on the throne, is named Poo-ta-la (Budh-laya), the residence of Budh; but ostensibly he professes and performs the rites of the ancient religion of China, and, at the appointed times, in the capacity of high priest, testifies his gratitude to heaven by offering up the fruits of the earth, and the flesh of certain animals considered as the most useful, as the horse, the ox, the sheep, the hog, the dog, and the domestic fowl. At such times all labour is suspended,—the public offices and courts of justice are shut up,—and a general festival prevails throughout the whole empire. The vernal ceremony of the emperor holding the plough, is rarely had recourse to in modern times.

The magistrates perform their devotions in the temple or hall dedicated to Confucius; and the usual oblation to his memory is that of a hog, as being the most useful animal known. The ceremonies are performed before a tablet placed on a pedestal, on which is written the name of the philosopher; and at the foot of the pedestal a grave is dug to receive the hair and offals of the animal, that no part of it should fall to unworthy purposes. To this temple every magistrate, on entering upon his office, goes with his official brethren, and, in their presence, after the usual homage to the emperor, professes himself a grateful adherent to the doctrines of the illustrious master, which ceremony amounts to the taking the oaths of fidelity and allegiance to the sovereign. Pere Intorcetta, in his treatise *De Cultu Sinensi*, has translated the whole ceremony from a Chinese author. It is very curious, and bears a marked resemblance to the Catholic ceremony of high mass. They burn incense—pour out libations of wine—chant solemn hymns, accompanied with instruments—read aloud a panegyric on his memory—prostrate themselves before the tablet; and then proceed to feast on the oblations, and to drink each of the “cup of felicity.” (*Intorcetta de Cultu Sinensi*.)

The common festival of all savage nations is the

time of full moon; and the common people of China are still barbarous enough to hold this festival by keeping up a noise and riot the whole night. But the grand festival in which all China partakes is that of the New Year, when families visit each other, exchange mutual compliments and present, abstain from all labour for several days; and every Chinese, however poor, contrives at this time to treat himself and his family with new dresses. His house is newly painted, and tablets of paper, variously shaped, adorn the walls of his apartments. On new-year's day, every Chinese strictly watches his own conduct, and everything that befalls him, being persuaded that whatever he does on that day will influence his conduct during the whole year. An universal holiday prevails—all labour is suspended—and nothing but feasting, rejoicing, music, and firing of crackers, prevail, from the midnight preceding the first day of their new year to the ninth day following. During this period, all is joy and festivity; yet, in this general scene of mirth and conviviality, to the credit of the Chinese it ought to be noticed, that instances of intemperance or inebriety rarely occur.

The festival of the new year is followed by another of a similar kind, which is called the festival of the lanterns. It commences two days before, and continues two days after the first full moon of the new year. All China is then in a blaze. Every house and every village, all the shipping on the canals and rivers, every Chinese, however poor, contrives to light up his painted lantern on these days. Transparencies in the shapes of birds, beasts, fishes, and all kinds of animals, are seen darting through the air, and contending with each other; some with squibs in their mouths, breathing fire, and others with crackers in their tails; some sending out sky-rockets, and others rising into pyramids of party-coloured fire; and others again bursting like a mine with violent explosions. A Chinese knows not why, nor makes any inquiries wherefore these things are. It is an ancient custom, and that is enough for him. The inscriptions on these lanterns would seem to point out its religious origin. The most common runs thus, *Tien-tee San-sheai, Van-lin, Chin-tsai*, “Oh heaven, earth, the three limits, and thousand intelligences, hail!” (*Barrow's Travels in China*.—*Macartney's Journal*.—*Du Halde and Grozier*.)

The basis, however, of the ancient Chinese religion, and which forms, as it were, the link which connects it with the government, is the obedience which children owe to their parents, the respect which is due from the young to the aged, and from the living to the dead, in the strict observance of which all other virtues are concentrated; for these are not to be considered as moral duties only, but political and religious ordinances. Every family of condition endeavours to build a temple to the memory of its ancestors; and all persons, not lost to every sense of duty and devotion, visit the tombs of their parents on a certain day in the spring of the year. Never were institutions more innocent in their intention, more blameless in practice, more amiable in their object, or better calculated to produce beneficial results, by recalling pleasing recollections, subduing the passions, and bringing the mind to that

China.

China. calm and tranquil state to which the memory of departed parents usually disposes it. The love and tenderness of departed parents are among the best impressions of the human mind; "Bind them," says Solomon, "continually about thine heart;" yet the bigoted Dominicans quarrelled with the Jesuits for allowing their Neophytes to honour the memory of departed relations. They represented it as a crime to pluck away the grass and weeds that might have grown around a parent's tomb, and to scatter flowers on a relation's grave; to meet together, and regale themselves with those dainties of which the deceased would have been partaker if alive; fulfilling thus the precept of Confucius, which inculcates the same respect to the dead as if they were living. To support his parents while alive, to bury them decently when dead, to visit their graves at the appointed time, are three indispensable duties of a pious son, by which he proves his gratitude, his sorrow, and his veneration.

There are few families of which some member, in a series of years, has not risen to rank and fortune. Such a one is particularly careful, in obedience to the precept in the ancient book of rites (*Lee-kee*), before he builds a palace, to erect a temple to the memory of his ancestors. To this temple, at particular seasons, all the branches of the family repair together, old and young, rich and poor, high and low—the first officer in the state and the day-labourer. Here all distinction for the time is laid aside, save that of age, which is always revered; and he, over whose head has passed the greatest number of years, takes the precedence in making the oblations, and at the subsequent entertainment given at the expence of the more wealthy members of the family. From five to ten thousand persons sometimes meet together on such occasions.

Whether it be the effect of superstition, or of real feeling, or considered as a religious duty, no people observe so much external attention to the memory of the dead as the Chinese. They even move their coffins from the place they have been interred, if the situation be gloomy or the ground swampy. Everywhere in China may coffins be seen exposed on the surface of the ground, because the surviving relation has not been able to fix upon a propitious spot to raise the tomb for its reception. These coffins are generally made of wood sufficiently thick to plank a first-rate man of war. A Chinese usually keeps his coffin by him in the house as a piece of furniture. He contemplates with pleasure the *angusta domus* which is to receive his last remains; and he tries it on just as he would try on a new coat. They believe in a future state of rewards and punishments, but their notions on this head are so vague and mixed up with those of the Boudhists and Brahmins, that it is difficult to say what were the precise tenets of the ancient sages respecting a future state of existence.

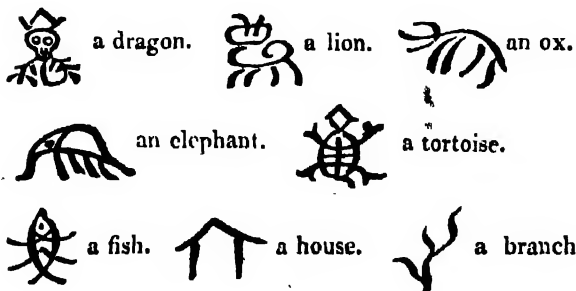

Among the religious superstitions of the Chinese, partly native and partly exotic, may be ranked the almost universal observance of lucky and unlucky days, which are duly registered in the imperial calendar. No marriages, no funerals, no contracts, in short, nothing of importance, must be undertaken on an unlucky day. Even his Imperial Majesty must

China. be governed in his movements by the Board of Astronomers. Another universal superstition is the *fung-shui*, wind and water, which relates to the exact line in which the roof of a house must be placed, in order to preserve its own security and its owner's prosperity. The Chinese conceive that a peculiar virtue resides in the odd numbers; thus they reckon *three* powers—heaven, earth, and man; *three* lights—the sun, moon, and stars; the *three* relations—a prince and his ministers—a father and son—a husband and wife. *Fo* has his *three* precious ones, and the *Tao-tse* their *three* pure ones, in which the Jesuits discovered the Holy Trinity. The temples of these sectaries have *three* quadrangular courts, the buildings around which contain the *three* classes of spirits, celestial, terrestrial, and infernal. They reckon *seven* ruling powers—the sun, moon, and five planets; *nine* is as efficient and mysterious a number as among the Hindoos; but *five* appears to be the number which is supposed to exert the most extensive influence. The *five* great virtues often spoken of in the ancient classical books are *charity, justice, good manners, prudence, and fidelity*. They reckon *five* domestic spirits; *five* elements; *five* primitive colours; *five* seasons of the year, over which are *five* presiding spirits; *five* planets; *five* points of the compass; *five* sorts of earth; *five* precious stones; *five* degrees of punishment; *five* kinds of dress, &c. (*Hist. Gen. de la China*.—*Mém. Chin. Intorcetta de Cultu*.—Morrison's *Dict.* &c.)

It is perhaps impossible for the Chinese themselves to determine what portion of their present mixed religion and superstitions belong to their ancient institutions, and what has been borrowed from other people. This, however, is not the case with their language: their speech and the character in which it is written, have maintained their primitive purity, and may be considered as exclusively their own. This language, more than any thing besides, stamps them as an original people. It has no resemblance whatsoever to any other language, living or dead, ancient or modern. It has neither borrowed nor lent any thing to any other nation or people, now in existence, excepting to those who are unquestionably of Chinese origin. The written character is just now as distinct from any alphabetical arrangement, as it was some thousands of years ago; and the spoken language has not proceeded a single step beyond the original meagre and inflexible monosyllable. Our countrymen have at length fathomed this hitherto mysterious, and, as it was supposed, unattainable language, the acquirement of which had long set at defiance all the talents and industry of foreigners, and was said to employ the whole lifetime of the natives; to them it is owing that we are now able to give some intelligible account of it. In fact, those insurmountable difficulties turn out to be altogether visionary. The laudable industry of Dr Marshman and Mr Morrison has supplied us with grammars and dictionaries of this singular language. They have not only placed the treasures within our reach, but given us the key to unlock them, though in an uncouth and unsystematic manner,—a defect which, however, is likely to be soon remedied by Mr Manning. As the subject is almost new in this country,

China. we shall endeavour to give as concise and comprehensive a view of it as our limits will admit, and such as may not only convey a correct notion of the singular nature and construction of the written character, but may be of some use to those who shall engage in the study of it.

The philologists of China speak of knotted cords, twisted from the inner bark of trees, being made use of originally to register events; but as this period is carried back to the fabulous part of their history, it only deserves notice from the remarkable coincidence of a nation having been discovered, many thousand years afterwards, on a different continent, and the antipodes almost of China, who were actually in the practice of using the same means for the same purpose. The second step towards the formation of a written character, by the invention of the *quo* or digrams of Fò-he, is perhaps entitled to as little consideration as the knotted cords. As a language they must have been too complicated, and the supposed use of them too refined, for a people in so rude a state as the Chinese represented themselves to have been in the time of that chief. It is generally thought, that the written character was first suggested in the reign of Hoang-tee, the third from Fò-he, and that the figures on a tortoise back first gave the idea. Mr Morrison says, that a person named Paou-she, who lived about the year of the world 2900, is considered as the father of letters, and that nine-tenths of his characters were hieroglyphic; he means to say, rude representations of the thing signified, which, in point of fact, may be considered as the first attempt of all uncivilized people to express their ideas to the eye. At a later period, we find several accounts of alterations and new suggestions in the characters, one making them to imitate the lines of the dragon, another the flowing lines of worms and snakes, a third the prints of birds' feet, a fourth of leaves, branches, roots, &c. all of which would appear to be nothing more than so many attempts to reduce the rude figures of objects to a more convenient and systematic form for general utility. Enough still remains on ancient seals, and vases for sacred purposes, to show the original state, or nearly so, of the Chinese characters, and to trace the changes that have taken place from the picture to the present *symbol*. These ancient characters are to be met with in numerous Chinese books, and a collection of them is contained in Pere Amiot's *Lettre de Peking*, from which the following are extracted. They are called the *Kou-wen*, and are the most ancient characters that are known:

of a tree.

a window.

a bow.

China.

to shoot. A multitude of similar descrip-

tion is to be found in books of philology, being obviously the rude representations of the several objects they are meant to express.

From these rude imitations of objects Chinese writers trace the progressive steps to a more abbreviated and convenient form: thus,  the sun, is

now.  the moon,  a moun-

tain, now  mouth,  .

 a field, now  a horse, now

 the eye, now  the

ear, now  a chariot, now  .

 a boat, now  a sheep, now

 a bow, now  the dragon is still

the complicated character , and the tortoise

The qualities of objects could only be marked down by arbitrary signs or symbols, which, however, when once settled by convention, were equally expressive with the pictural resemblances of those objects. Many modifications, however, such, for example, as crooked, straight, above, below, great, little, &c. were capable of being expressed to the eye by particular characters, appropriate to their modifications

 one,  two,  three, 

hooked,  covered, sheltered, protected, &c.

but symbolical representations of this kind could not be sufficiently numerous to embrace all the qualities and modifications of objects.

The first attempt at a regular system of classifica-

China. tion of the characters, which the Chinese had invented for expressing their ideas, is stated to have been that of dividing them into nine classes, called the *Lee-shoo*, and afterwards into six, called the *Lieou-ye*.

- 1st Class, contained all those which had been reduced from the rude picture of the object to a more simple form, as the sun, moon, a man, a horse, &c.
- 2d, Those which pointed out some property belonging to the object, as great, small, above, below, &c.
- 3d, The combination of two or more simple objects or ideas to produce a third, resulting from their union.
- 4th, Those whose names, when sounded, were supposed to imitate the sound of the objects expressed by them.
- 5th, Those which give an inversion of the meaning by inverting the character; and all those used in a metaphorical sense.
- 6th, This class seems to include all those characters that are merely arbitrary, and which cannot be brought under any of the preceding divisions. We shall explain these classes by examples.

This ill-digested and obscure arrangement was soon abandoned for another not much better,—that of classing the characters according to their sounds or names. As these names were all monosyllables, and as each monosyllable began with a consonant, with very few exceptions, and ended with a vowel or liquid consonant, the number of such monosyllables was necessarily very limited; by our alphabet, the whole of them might be expressed in about 330 syllables; but as necessity taught the Chinese to employ in early life the organs of speech and hearing, in acquiring a greater nicety than most nations have any occasion for, they were able to swell the number of their monosyllables, by means of intonations and accentuations, to about 1200 or 1300. As soon, therefore, as the number of characters exceeded the number of words, it is evident that any *verbal* arrangement must be attended with uncertainty and confusion; if, for instance, they had 10,000 characters and only 1250 words, the same word must be applied to eight different characters; and as the latter now, in Kaung-he's Dictionary, exceeds 40,000, each syllable in the Chinese language must, on an average, represent thirty-two different characters; and, in point of fact, there are syllables that give the same name to sixty or eighty different characters.

It is difficult to conceive, therefore, without the assistance of an alphabet, how they could possibly contrive to class the characters in a dictionary according to their *names*, and by what means they could ascertain the name of a character which speaks only to the eye. To discover this, they seem to have had recourse to three different methods; the first was to place at the head of a list of characters, having the same sounds, some common well known character, and to mark them severally with their respective intonations; the second method was that which is still used in all their dictionaries. It consists in writing after the character, whose sound is sought for, two common characters, of which the initial

China. sound of the first added to the final sound of the latter, produces a third; as from the *m* of *moo* and the *ing* of *ting*, is compounded the third or new monosyllable *ming*; and, in the same way, from *ting* and *ke*, would be formed *te*, &c. The two characters, so employed, are called *tse-moo* or “mother characters,” and the third produced from them *tsé*, or “the child.” The third method was, by means of a modified Sanscrit alphabet, or series of sounds, which was introduced into China since the Christian era, by some priests of Budh, “to give currency,” says one writer, “to the books of Fo.” This system is described in the introduction to Kaung-he's Dictionary, though it is never used, and but very little understood. The Chinese, indeed, reprobate the idea of changing their beautiful characters for foreign systems, unknown to their forefathers. “It appears to me,” says one of their writers, “that the people of *Tsan* (Thibet, from whence they derived the system of initials and finals) distinguish sounds; and with them the stress is laid on the sounds, not on the letters. Chinese distinguish the characters, and lay the stress on the characters, not on the sounds; hence in the language of *Tsan*, there is an endless variety of sound; with the Chinese, there is an endless variety of the character. In *Tsan*, the principles of sound excite an admiration, but the letters are destitute of beauty; in China, the characters are capable of ever-varying intelligible modifications, but the sounds are not possessed of nice and minute distinctions. The people of *Tsan* prefer the sounds, and what they obtain enters the ear; the Chinese prefer the beautiful character, and what they obtain enters the eye;” and the Chinese are right; for, unless with their character they gave up their monosyllables, they might almost as well have no written language at all; as, if written alphabetically, it would be wholly unintelligible. The written character assists their meagre monosyllables,—an alphabet would completely destroy them. The written character, however, has probably been the means of fixing the spoken language in its primitive monosyllabic form, as the least change or inflexion of the spoken language, must at once and for ever destroy the connection between it and the written character; and this connection, by the way, is no mean proof of the antiquity of the present symbols. (Pref. to Morrison's *Dictionary*.—Barrow's *Travels in China*.)

These symbols are now reduced to a regular and complete system, which renders the study of the language comparatively easy. A certain number of characters have been selected, which the Chinese call *Tse-poo*, “superintending or directing characters,” and sometimes *Shoo-moo*, or the “Eyes of the Book,” which, considering them as composing an index to the book, is no bad name. The Jesuits have given them the name of *keys*, and sometimes *elements* or *radicals*, there being no character in the whole language, into the composition of which some one or other of them do not enter. This number, according to the classification now in general use, consists of two hundred and fourteen, and they are divided into seventeen chapters or classes; beginning with those keys or elements that are composed or formed of *one* stroke of the pencil, and ending

China.

with those (of which there is only one) composed of seventeen strokes. Plates LIV. LV. LVI. comprehend the whole of these keys or elements, with their several names and significations. When these two hundred and fourteen keys or elements are once become familiar to the eye, there is no great difficulty in detecting them in any of the characters into which they may enter, and without some one or more of which, no character can be formed. They will be found to stand more frequently on the left side than on any other part of the character, though they also take their stations sometimes on the right, sometimes in the middle, frequently at the top, and occasionally at the bottom; but a little practice and a ready knowledge of these keys, will point them out at once. Thus, in

1. 便 *pern*, "convenient," the key 亻 *jin*, "man" is on the left.
2. 助 *tsoo*, "to assist," has the key 力 *lee* on the right.
3. 全 *tseun*, "the whole," has the key 入 *joo*, at the top.
4. 兵 *ping*, "a soldier," has the key 八 *pa* at the bottom.
5. 愛 *gai*, "to love," has its key 心 *sin*, in the middle of the compound.

The dictionaries are divided into seventeen sections, headed respectively by the seventeen classes or keys, commencing with that class which has its keys of one stroke, and ending with that which is composed of seventeen strokes. The characters which each key governs, or to which it serves as the index, are also divided into classes, according to the number of strokes they contain, beginning at *one*, and proceeding regularly to the greatest number that any one is found to contain, *exclusive of the key*; and this number, together with the key character, being marked at the top of every page in the dictionary, afford a clue by which any character in the language may be turned to immediately, having first ascertained the *key*, and the number of strokes in the remaining part of that character. Thus in the above examples, the character *pern* will be found under the key *jin*, and, in the *seventh* section, there being *seven* strokes exclusive of the *key*; in the second, under the *fifth* section of the index *lee*; the third, under the *fourth* section of the index *joo*; the fourth under the *fifth* section of the key *pa*; and the fifth under the *ninth* section of the index *sin*.

This classification of the characters is extremely simple and easy; the chief object of it would appear indeed, to be like the *Linnean* system, that of giving facility to the finding in the dictionary the character

that may be wanted. The nature of Chinese symbols admitted, however, of a more beautiful, perfect, and philosophical arrangement, and might, indeed, have been made the most rational and complete system of pasigraphy or universal character, that has yet been attempted. It would seem, indeed, that the Chinese had this idea once in view, but, either through ignorance, pride, or caprice, they have entirely marred the plan, and nearly lost sight of it altogether. In the original adoption of the *shoo-moo*, or "book's eyes" (the *poo* or keys), they selected no less than 479 to serve as indices to the characters, the whole of which were marshalled under nine divisions. The *first* had a few only, consisting of a single line. The *second* embraced celestial objects, as the sky or firmament, the sun, moon, stars, clouds, rain, thunder, &c. The *third*, terrestrial objects, as earth, water, metals, hills, rivers, &c.; the *fourth*, man, and all the animal functions; the *fifth*, moving things, including all the rest of the animal creation; the *sixth*, the vegetable world; the *seventh*, productions of art and human industry; the *eighth*, miscellaneous; and *ninth*, characters of a doubtful genus, whose classification could not well be ascertained. Though this was a complicated, and in some degree an arbitrary classification, yet it comprehends a principle that, if it had been adhered to in simplifying the arrangement of the characters, the Chinese might have challenged the world to produce so beautiful and so philosophical a language as their own. This system, called the *Leu-shoo*, is that stated by Mr Morrison to have been invented by *Paou-she*.

After this the 479 keys or elementary characters were reduced to 214, and the characters themselves arranged under six divisions, as before-mentioned, the nature of which will be best explained by a few examples to each; they will tend to show how much more might have been accomplished in this practical approach to an universal character.

1st Class. The rude representation of the object may now be considered as no longer to exist, but this class consists generally of simple characters, and almost all the great objects of nature are found among the keys or elements which enter into their composition; this may be called the *Imitative Class*.

2d Class. Under which are comprehended those characters which point out the quality or property of

an object, as 上 *shang*, above 下 *shea*, below.

Thus also 一 *ye*, one, is used to represent unity,

concord, &c. 丨 *kuan*, straight, upright; 丿 *quay*,

hooked, and generally such characters whose meaning can be extended, in a metaphorical sense, as far as the object represented would admit of being so applied, as, for instance, a line drawn through a square thus,

中 signifies *middle*, or any thing divided into two

China.

China. parts; the same character, in a figurative sense, expresses moral rectitude, good dispositions, &c. This class may therefore be called the figurative.

3d Class. Under this class might have been ranked all those compound characters which, if the numbers were properly selected, would have given that peculiar beauty and expression to the language which, even in its clumsy and imperfect state, the Chinese still pretend to feel, by employing significant characters, each of which should be connected with the idea to be conveyed by their union. One half of the language, at least, might thus have been composed, and presented a series of symbols, every one of which would have been intelligible to the eye; whereas not one-sixth part at the most, some say not one-tenth, of the compounds, have any relation to their component parts. A few examples will serve to show how much might have been done by attending to a philosophical composition of the compounded characters. Thus,

人 *jin*, man, and 言 *yen*, word, forms the compound 信 *sin*, sincere: 日 *je*, the sun, and

月 *yué*, the moon, 明 *ming*, splendour:

中 *tchung*, middle, and 心 *sin*, heart,

忠 *chue*, fidelity: 人 *jin*, man, and 田 *tien*,

a field, 佃 *tien*, a farmer: 田 *tien*, a field,

and 力 *lee*, strength, 男 *nan*, male

kind: 耳 *erl*, the ear, and 止 *tchei*, to stop,

耻 *chce*, shame: 口 *koo*, mouth, and

金 *kin*, gold, 吟 *kin*, volubility of

speech: 言 *yen*, word, and 寺 *shee*, tem-

ple, 詩 *shee*, verses, poetry: 分 *fen*, to

divide, and 貝 *pei*, riches, 貧 *pin*, poverty:

口 *yu*, an enclosure, and 人 *man*,

囚 *cheu*, a prisoner: 禾 *ho*, rice, and

口 *koo*, mouth, 和 *comfort*: 一 *ye*,

one, and 大 *ta*, great, 天 *tien*, heaven

or God: 从 *tcheou*, a bamboo, and 郎

a slap, 節 *chee*, to govern: 春 *keu*,

high, and 馬 *ma*, horse, 驕 *kheu*, proud.

4th Class. The characters arranged under this class are such as embrace both the meaning of the object and the sound it is supposed to utter; and it includes objects animate and inanimate. The characters are all compounded of one of the elements to express the genus, added to one imitative of the

sound uttered by the object. Thus 水 *shuee*, wa-

ter, added to 工 *koong*, forms the character

江 *kyang*, which denotes a rapid stream, expressive, as they say, of water rushing with violence;

and 可 *ho*, a river with 水 *shuee*, water,

makes the compound 河 *ho*, a river, the name

of which is said to imitate the sound. To this class may also be added those objects in the animal kingdom whose generic character can be expressed by one of the elements, and the species by some other character that shall convey its name merely by the sound of the latter character. If, for instance, to the generic character, *bird*, be added another character whose name or sound is *go*, the new compound will also be named *go*, and will signify a goose; if, to the same character *bird* be added another named *ya*, the compound will also be *ya*, and will signify a duck; if, to the generic character *tree*, be added the appellative *pe*, the compound will be named *pe*, and signify a cypress; with *tao*, it will be called *tao*, and signify a walnut tree; and with *lieou*, it will retain the name of *lieou*, and signify a willow. In this class may also be comprehended all foreign names written in the Chinese characters, to which, in order to mark them as destitute of meaning, they usually annex on the left side the character signifying *mouth*. Thus the English word *strong* would require three

China.

China.

characters, *se-te-lung*, and, with the *mouth* prefix-ed, would be written thus 吐 *se* 口得 *te*

龍

lung; but these characters, if the *mouth*was taken away, would be read by a Chinese—the *magistrate procured a dragon*.

5th Class. Consists of an inversion of the sense by an inversion of the whole or some part of the character; or it alters the meaning by giving a different name to the same character; or, lastly, the characters which compose it are used in a figurative or metaphorical sense. An European cannot readily comprehend the illusions or allegories that are frequently contained in a single character, though probably they are not more numerous than those which are found in any of the languages of Europe, rendered easy, and indeed not perceived, by early habit. The combined characters of the *sun* and *moon*, which, in a physical sense, expressed brightness, brilliancy, splendour, are also, in a moral or metaphorical sense, noble, illustrious, famous. The characters *heart* and *dead* form a third, which signifies *forgetfulness*; *fickleness* or *levity* is represented by a *girl* and *thought*; *attention*, by the *heart* and *totality*; *antiquity*, by *mouth* and the numeral *ten*; to *flutter*, is compounded of *word* and *to lick*; to *boast*, of a *mountain* and *to speak*. The *wife of a magistrate* is used metaphorically for an *accomplished lady*; a *wild boar* for *courage*; and a *tiger* for *ferocity*, &c.

6th Class. These characters are either arbitrary, or formed out of some distant or local allusion, most of which are inexplicable to the Chinese themselves. Thus, a *bamboo* and *heaven* form a compound, which signifies *to laugh*; *water* and *to go*, compose a character signifying *law*; *wood* and the *sun* form the word *east*; the character *woman* three times repeated may signify *adultery*, or *communicating with an enemy*. These may or may not be arbitrary combinations. We can explain why the compound of *wine* and *seal* should signify *marriage*, from the circumstance of *wine* being presented by the bridegroom to the bride as the *seal* to the contract; and why that of *girl* and *upright* should signify *concubine*, or inferior wife, because such a one must *stand* in the presence of her lord and master; also, why that of *woman* and *sickness* should signify *death*, because when the sovereign was sick, and *given over* by the physicians, he was left to *die* in the hands of *women*; but by far the greater part are utterly inexplicable.

Such, by the Chinese account, is the philosophy of their language; not very clear, it must be confessed, nor exactly calculated for practical facility; but, at the same time, approximating to a very beautiful system. That system has, to a certain degree, been preserved in the modern classification under the 214 elements. Thus, under the element or key which signifies *heart*, we shall find all the characters arranged expressive of the sentiments, passions, and affections of the mind, as *grief*, *joy*, *love*, *hatred*, *anger*, &c. The element *water* enters into all the compounds which relate to the sea, rivers, lakes,

swamps, depth, transparency, &c. The key or element *plant*, takes in the whole vegetable kingdom.

Yen, a word, enters into the composition of those characters which relate to reading, speaking, studying, debating, consulting, trusting, &c. All the handicraft trades, laborious employments, and a great number of verbs of action, have the element *hand* for their governing character. All this is perfectly intelligible; but, on casting a glance over the elementary characters, it will be seen that fully one half of them are utterly incapable of being formed into any generic arrangement; and one is surprised and puzzled to conjecture by what accident they could possibly have been included among the elementary characters, or even as indices to characters. The fact is, that, of the 214 characters thus employed, not more than 150 can be considered as effective; the rest being very rarely employed in the combination of characters. Of the 40,000 characters, or thereabouts, contained in the standard dictionary of the language, 60 of the elements govern no less than 25,000. The most prolific is the element *grass* or *plants* (No. 140), which presides over 1123 characters; the next *water* (No. 85), which has 1333; then the *hand* (No. 64), which has 1012. After these follow, in succession, the *mouth*, *heart*, and *insect*, each having about 900; then a *word*, a *man*, and *metal*, each exceeding 700; next a *reed* or *bamboo*, a *woman*, *silk*, a *bird*, *flesh*, *mountain*, &c., each governing from 500 to 600, &c. In the modern classification, therefore, of the characters, though probably intended as a more convenient instrument for reference in the dictionaries, so much of the natural arrangement has been preserved as will serve to convey to the eye, at once, the general meaning of a character; at least of such characters as are governed or fall under any of the principal elements. They have even gone beyond this. Feeling how much more capable of nice discrimination the eye is than the ear, the written character has been employed to mark distinctions, which, in an alphabetic language, would be impossible. Instead of the modifications of time, place, age, colour, and the like, by which sensible objects are affected, being expressed by so many epithets or additional characters, in the several stages of their existence, or the lights in which they may be viewed, the Chinese employ only one single character for each several modification of which an object or idea may be susceptible, whether in the physical or intellectual world. Thus they have the key or elementary character for *water* simply; another under that key for *salt water*, a third for *fresh water*, a fourth for *muddy water*, a fifth for *clear water*; and so on for *running*, *standing*, *deep*, *shallow*, and every other qualification that water is capable of receiving; and the same of love, anger, jealousy, ambition, &c.; all of which are expressed by their respective symbols combined with the element *heart*.

The colloquial language is not less singular than the symbolical characters; being, like the latter, exclusively their own; having borrowed nothing from, nor lent anything to, the rest of the world. The 330 monosyllables, each beginning generally with a consonant, and ending with a vowel, or liquid, or the double consonant *ng*, which, as we have observed, complete the catalogue of words in their

China.

China- language, are, by means of four modifications of sound, or intonation to each syllable, extended to about 1300; beyond which, not one of them is capable of the least degree of inflexion, or change of termination; and the same unchangeable monosyllable acts the part of a noun substantive, and adjective, a verb, and a participle, according to its collocation in a sentence, or the monosyllables with which it is connected. It is neither affected by number, case, nor gender; mood, tense, nor person; all of which, in speaking, are designated by certain affixes or prefixes to mark the sense. Thus the genitive of *love*, *gai*, is expressed by the particle *tié* set after it, as *gai-tié*, of love; the dative by *eu-gai*, to love; and the ablative by *tung-gai*, by or from love. The plural is expressed sometimes by the repetition of the noun, as *yin*, a man; *yin-yin*, men; *to-yin*, many men; *to-to-yin*, all men. Certain particles of number are also employed before nouns, which vary according to the nature of the noun. Thus *man* has *ko*, as *sau-ko-yin*, three men; most other animals *tchee*, as *liang-tchee-ma*, two horses; bodies with extended surfaces *tchiang*, as *ye-tchiang-tchou*, one table, &c. The number of particles so employed amount to about thirty. The final expletive *tsé* is added to nouns, not only to distinguish them from adjectives, but for the sake of euphony; as *pie-tsé*, a pipe; *fang-tsé*, a house; *ya-tsé*, a chair; the particle *tié*, the same which designates the genitive of the substantive, is set after the adjective or pronoun; as *ta*, he, with *tié* after it, becomes a possessive, *ta-tié*, his, &c. The gender of nouns is seldom necessary to be expressed in conversation, unless for the sake of removing ambiguity. When this is the case, *nan* and *neu* distinguish male from female, as *nan-yin*, a man; *neu-yin*, a woman. Adjectives admit of comparison in various ways. Commonly *ye yang* is used to express the positive, as *ye yang-hoa*, as good as, or equally good; the preposition *keng* forms the comparative, as *keng-hao*, better; and, with the addition of *toi* following it, the superlative, as *hao-toi-keng*, the best; a repetition of the positive also marks the superlative, as *hao-hao*, very good.

The personal pronouns *go*, *ue*, *ta*, I, thou, he, are made plurals by the addition of *mun*, as *go-mun*, *ne-mun*, *tu-mun*, we, ye, they. *Che-ko*, this, and *na-ko*, that, are the demonstratives.

The only tenses of the verb necessary to be distinguished are the present, past, and future. The past is formed by the particle *leau* set after it, and the future by *yan*, will or determination, or *tchong lai*, time to come. Thus *go gai*, I love; *go gai leau*, I have loved, or did love; *go yan gai*, or *go tchong lai gai*, I shall hereafter love. The negatives generally in use are *mo* and *poo*; as *yeu*, to have; *mo yeu*, not to have; *hao* good; *poo hao*, bad.

Such is the simple and inartificial language spoken by a mass of people equal in number to that of the whole of Europe. Its imperfection must be obvious, when it is considered that 40,000 distinct characters are represented by about 1300 monosyllabic sounds; but, as a good composition is intended only to be seen, the particles and expletives, necessary in familiar conversation, are all omitted; if such writing were read aloud, it would scarcely be intelligi-

China- ble, and, at any rate, full of ambiguity. Indeed, it frequently happens, that, in reading a paper, the auditors are assisted by the reader making, with a motion of his hand in the air, or with his fan, the shape of the character, or, at least, the key of it, to remove any ambiguity. This, in conversation, is obviated by the use of certain expletives. For instance, when a man is speaking of his father, which is *foo*, a monosyllable that has seventy or eighty other meanings besides that of father, a Chinese will say *foo-chin*; and, instead of *moo* for mother, *moo-chin*; the syllable *chin*, signifying *kindred*, removes at once all doubt as to the meaning of the speaker; but the *chin*, in writing, is wholly unnecessary, and would be left out; the character signifying *father* being totally different from any other character that may have the name of *foo*. A foreigner, not always aware of this, is liable to many equivokes in speaking the language. Thus a missionary, requesting to be allowed to pass the night at a peasant's house, asked for a *young girl* to sleep with, when he meant only to ask for *a mat*; and another told the Emperor he *served three wives*, when he meant to say so many *churches*. (Barrow's *Travels in China*.—Morrison's *Dictionary*.—Marshman's *Clavis Sinica*.—Fourmont's *Meditationes Sinicae*, &c.)

One of the most remarkable features of Chinese Literature. policy, is the encouragement given to the cultivation of letters, which are professedly the sole channel of introduction to political advancement in the state, and to the acquirement of office, rank, and honours of almost every description. The pursuits of literature throw open the highest offices in the state to the lowest of the people; and, with a few exceptions of particular favourites, or of Tartars connected by blood with the imperial family, it would appear that honours and offices are generally bestowed according to merit. With the prospect of such rewards, the number of competitors is very great, and a taste for letters is almost universally diffused among all ranks and denominations. Schools abound in every town and village, and the best education that China affords is to be had on the most moderate terms. In every part of the empire, certain magistrates are appointed by the government to call before them all candidates for employment, to direct them in their studies, and twice a year to hold public examinations, when small presents are distributed to the most deserving. As a farther encouragement to literature, the press is left free to all, and any one may print what he pleases, taking his chance for the consequences. That this unrestrained liberty of the press should exist in one of the most arbitrary governments that is known, is a remarkable phenomenon in the history of nations. No previous licence is required; no restrictions are imposed; though the publication of books is made amenable to certain regulations established by law. In general, crimes, and their corresponding punishments, are clearly and minutely defined in the *Laws of China*, but the law which regards the press is left, perhaps intentionally, vague and uncertain. According to the *Leu-tce*, "Whoever is guilty of editing wicked and corrupt books, with the view of misleading the people; and whoever attempts to excite sedition by letters or hand-

China. bills, shall suffer death by being beheaded; the principals shall be executed immediately after conviction, but the accessaries shall be reserved for execution at the usual season." And further, "All persons who are convicted of printing, distributing, or singing in the streets, such disorderly and seditious compositions, shall be punishable as accessaries."

These severe laws are by no means a dead letter; numbers have been executed in virtue of them. Three unfortunate authors were punished with death, and their families banished, by that great patron of literature, Kien-lung, in three consecutive years, for publishing books that no European government would have deigned to notice; but political discussions are least of all palatable to despotic governments, and are easily brought under the charge of constructive treason,—a crime that in China is never pardoned.

The instances, however, that occur of severity of punishment, seem to have little effect in diminishing the number of publications, and are not more hostile to the liberty of the press in China, than the occasional punishment of a jail, for libel, is destructive of that liberty in England. A writer in a popular periodical journal says, that thousands of novels and moral tales, amusing stories, laughable comedies, moral precepts from ancient sages, and exhortations from living sovereigns; popular songs, fables, and romances; books of receipts to heal the sick and to pamper the appetite; predictions of the weather, and of good or bad luck; manuals of devotion, of religious rites, and rules of good-breeding; almanacks and court calendars, are the lighter sort of publications which issue daily from the press in Peking, and other great cities of the empire. All ranks in China read, and find it a cheap luxury; the more bulky and expensive works, as those on history, philology, jurisprudence, &c. are sometimes published by subscription, but are supplied to the libraries of the magistrates by the government. Libraries are seldom formed to any great extent by individuals. The grand collections of history, philosophy, and other standard national works, published by the direction of the sovereign, under the superintendence of the *Hou-lin*, are distributed to the princes of the blood, the viceroys of provinces, presidents of departments, and to the learned of the empire, but are rarely met with in the libraries of private individuals.

We can form no estimate of the state of literature in China, from the paraphrastic translations of ill-chosen books, and the commentaries on them, made by the Jesuits and other Catholic missionaries; the trite morality of Cong-foo-tse and Men-tse; the wise sayings of this emperor, and the wicked doings of that, which are contained in the *Ou-king* and the *Se-Choo*, their ancient canonical books, convey no better idea of the state of China or of its literature, than the Domesday Book does of that of England. The *Tong-kien-kang-moo*, or General History of China, by Pere Mailla, may be considered as the most important of missionary translations. Some of the Odes of the *Shao-king*, by Pere Premare, are curious, as exhibiting specimens of their poetry 4000 years ago. The *Eloge de Moukden*, a poem by the Emperor Kien-lung, by Pere Amiot, is no bad specimen of

modern poetry, for such it is, though, like Ossian, it is unmeasured poetry. Of the merits of his *Conquest of the Miao-tse*, by Mr S. Weston, through the medium of a French translation, we are unable to form any just idea. Works on philology, and commentaries on the characters of the languages, are endless; and, on this subject, many curious observations will be found in Pere Amiot's *Lettre de Peking*, and in various parts of the *Mém. concernant les Chinois*. The little novel of *Hao-kiau-tchuun*, edited by Dr Percy, from the papers of an English supercargo, is so charming a specimen of that kind of writing, as to make us regret that we have not more. The orphan of the house of Tchao was not unworthy of the tragic muse of Voltaire, and yet it was the only specimen of this kind of composition that had appeared in an European dress till the present year. We have now another drama more closely and more faithfully translated by Mr Davis, taken from the same collection of one hundred dramas in which the *Orphan* is found. The *Mémoire sur l'art Militaire*, although collected from the works of the greatest Generals, was unworthy the trouble bestowed upon it by Pere Amiot; the military movements, as there represented, are more suitable for mountebanks, tumblers, and posture-makers, than for soldiers; the Chinese are, in fact, the worst soldiers in the world. The same thing may be observed with regard to his Treatise on Chinese Music, a farrago of trash, not one word of which either he or his Chinese author understood. We have some curious matter on the rites and ceremonies of the several religious sects in China, by Pere Intorcetta and La Favre, and on various subjects in the *Hist. de l'Academie des Inscript. et Belles Lettres*, by Mss. Freret and De Guignes; and especially of books translated into Chinese from the Sanscrit, which are to be found in the temples of Fo. These volumes would, no doubt, throw much light on the state of Hindostan before the Mahommedan irruption, which created such havoc and devastation of Hindu literature. It was chiefly with the view of examining these documents, for the better illustration of the history, religion, and literature of India, that Sir William Jones set about learning the Chinese language. De Guignes ascertained, that the priests of Fo were in possession of 5400 volumes on the religion of India in the sixth century of the Christian era. Five centuries before this, another priest translated twenty-three different books on religion into Chinese, which were lodged in the library of the temple of Sei-gan-foo; and, about the same time, one of a party of pilgrims, who travelled from this city to Benares, from thence to Ceylon, and returned by sea to Canton, published a relation of his travels, under the title of *Fo-quo-kee*, a History of the Kingdom of Fo, of which there is a copy in the King's library at Paris. Frequent mention is made in the *Tong-kien-kang-moo*, and other histories of China, of priests being dispatched into India, in the early periods of the Christian era, for the express purpose of procuring Hindu writings, chiefly those on religion and astronomy; from which it may be concluded, that, if the Hindus really had any thing valuable which perished by Mahommedan bigotry, it may still have survived in China.

Among the works of which a translation would be

China.

China.

most desirable, may be mentioned the *Tai-tsing-yetung-tse*, a complete Encyclopædia of Arts and Sciences, in 200 volumes, published under the sanction, and by the authority, of Kien-lung; for, though we have nothing to expect from the state of science in China, they far surpass all Europe in many arts, and are in possession of others of which Europe is entirely ignorant. The *Ta-tsing-hoc-tien*, another work containing the whole Institutes of this vast Empire, with all the regulations of the several departments of government; the whole system of jurisprudence, of revenue, and finance, taxation, &c. would afford an interesting picture of this extraordinary nation. Of this curious work, also published by the authority of Kien-lung, there is a very general abstract by M. Cibot, in the 4th volume of *Mém. sur les Chinois*. This abstract, and the recent translation of the *Ta-tsing-leu-lee*, by Sir George Staunton, enable us to form a tolerably correct notion of the machinery by which the multitudinous population of the largest empire on the face of the earth has been uniformly kept in motion, and performed its several functions for the last four thousand years.

The desiderata of Chinese literature in Europe are some of their lighter productions, which our increasing knowledge of the Chinese language will no doubt soon supply. The dictionary of De Guignes, compiled by the Jesuits, and the more important dictionary of Kang-hee, called the *Tse-tien*, now under publication in the English language by Mr Morrison, a *Chinese Grammar* by the same gentleman, and the *Clavis Sinica*, ponderous as it is, by Dr Marshman, with various translations of these missionaries, have rendered the study of that language so easy, as to leave no excuse for the continuance of that total ignorance which has, for two centuries nearly, prevailed among the East India Company's servants stationed in China. If any proof were wanting of the possibility of a speedy acquirement of the Chinese language by a foreigner, the circumstance of Mr Davis having translated several Chinese works, both in poetry and prose, may be adduced as an example in point. Before he had been two years in Canton, this gentleman had acquired a sufficient knowledge of the language to enable him, with occasional assistance of a native, to translate several pieces of poetry, two or three novels, and, which is probably most difficult of all, a Chinese drama, which has recently been published in London. Many years ago, Sir George Staunton was able to carry on a correspondence with the officers of government at Canton, —to translate the *Ta-tsing-leu-lee*, —the journal of a Chinese officer through the vast regions of Tartary, by the Barkal Lake, as far as the Kerghis hordes, near the borders of the Caspian, which we hope to see published. It corroborates, we understand, in an extraordinary manner, the observations of Bell, which, indeed, were never called in question; and is the more curious, as they both travelled in the same year, and must have crossed each other on the way. Sir George has, besides, we believe, translated a Chinese drama, and two or three short tales from a collection called *Tsing-tsu*, or "Histories descriptive of the Passions." Mr Manning, whose name we have already noticed, has made himself perfect

China.

master of the Chinese language, an account of which he intends to publish. We mention these to show, that there is neither any difficulty in acquiring a knowledge of the Chinese language, nor want of inducement to prosecute the study of it. Sir George Staunton is alone in possession of from 3000 to 4000 volumes.

Europeans have been deceived as to the vast number of characters in this language, which was supposed to create its difficulty. In the great dictionary of Kang-he, there are not more than 40,000 characters, of which about 36,000 only are in use. The lexicon of Scapula contains about 44,000 words; Ainsworth's dictionary 45,000, and Johnson's about the same number. The whole works of Confucius contain only about 3000 different characters. The *Leu-lee* may have, in the whole, about 100,000 characters, but not more than 1860 different ones throughout the whole work. Where, then, can there possibly be any difficulty?

The origin of Chinese poetry is indicated by the Poet component parts of the character employed to express it,—*words of the temple*,—short measured sentences, delivered as instructions to the people,—such are those in the ancient writings, and such chiefly are the moral maxims of Confucius. It is so far from being true, as Grozier flippantly asserts, "that a learned man writing good verses, would be considered in the same light as a dragoon officer playing well on the fiddle," that there are few men having any pretensions to learning, who do not write verses. The several odes and didactic poems of Kien-lung, were quite sufficient to make poetry fashionable, if there were no taste for it among the people; but all are fond of poetry. We have before us the translation of part of an Ode on England and London, written by a common Chinese servant, brought over by a gentleman from Canton, in which are many just observations, with accurate and concise descriptions; the climate, he says, is cold, and people live close to fires; that the houses are so lofty that you may pluck the stars. Kang-he made the same observation to the Jesuits, and supposed that Europeans lived like birds in the air, for want of space to build upon. Our Chinese proceeds to say, that the virtuous read their sacred book, and (*pe lee to God*) pray to God; that they hate the French, and are always fighting with them; that the little girls have red cheeks, and the ladies are fair as the white gem; that husbands and wives love each other; that the playhouses are shut in the day and open at night; that the players are handsome, and their performance delightful, &c. The nature of the character is well adapted to that expressive kind of poetry which pleases the eye of a Chinese, by selecting such as are most comprehensive, or such as allude to some ancient custom, or such as can be used in a metaphorical sense: for instance, "the rushing of water down a precipice, roars like thunder," is expressed by a single character; and that which signifies "happiness," reminds him, by its component parts, of his guardian angel,—of the benefits of union and concord,—of plenty, signified by a mouth over a cultivated field. The intercalary moon is expressed by the character *king* placed in that of

gate, because on such an occasion it was the ancient custom for the king to stand in the door. Thus, also, a man and word express fidelity; fire and water, calamity; eye and water, tears; heart, truth, and words, sincerity; word and nail, a bargain; beauty and goodness are signified by a character composed of a young man and an infant; a flatterer, of word and to lick; a kingdom is expressed by a square or space within which is a mouth and weapons, alluding, perhaps, to arms and counsel, being the best protection of a state. But though the sense of seeing seems to be that which is rather addressed in Chinese poetry than the sense of hearing, yet they have their rules both of rhyme, and measure, and quantity, the last of which is given by the tones or accentuations, which are entirely modern. Among the specimens of ancient poetry from the *Shoo-king*, the following is an address of the Emperor Chun to his ministers:

*Koo, kuong khée tsai
Yuen shyeu khée tsai
Puh kuong hee tsai.*

When the chief ministers delight in their duty,
The sovereign rises to successful exertion,
A multitude of inferior officers ardently co-operating.

To which the ministers responded in the same strain:

*Yuen shyeu ming tsai
Kóo kuong lyang tsai
Shyeu tsé khang tsai.*

When the sovereign is wise,
The ministers are faithful to their trust,
And all things happily succeed.

The *Shee-King*, or collection of odes, upwards of 300 in number, is of a higher strain, one of which, on marriage, has been beautifully versified by Sir William Jones. The lines consist of no definite number of syllables, some containing three, some seven, but the greater part are limited to four. The rhyme is equally irregular, some having none, in others every line terminating with the same word; sometimes six lines rhyme in a stanza of eight, occasionally four, three, and sometimes only the first and last. Four lines in the stanza, and four characters in each line, seem to be the most common measure in ancient poetry; but many odes of the *Shee-king* extend the stanza to eight, ten, or twelve lines. At present, five and seven characters are the most common number in the line; the former having the stanza of sixteen, the latter generally of eight; the rhyme seems to be entirely arbitrary. There is not much sublimity of mind or depth of thought in these odes, but they abound with many touches of nature, and are exceedingly interesting and curious, as showing how little change time has effected in the manners and sentiments of this singular people. A number of rules with regard to the tones have recently been introduced, which would require more space to describe than they seem to deserve. As a didactic poem, the *Eloge de Moukden* of Kien-lung, appears by no means to be destitute of merit; it is considered in the Chinese to be highly poetical, though not written in measured lines; and it con-

tains much beautiful description. His Ode on Tea is of a humbler cast, and some lines on tea-cups, generally ascribed to him, are, in an English dress we have seen, absolute nonsense: the translator has, in fact, mistaken the whole meaning.

We give the following from Grozier's collection, as no unfavourable specimen of modern poetry. It may be called the Contented Philosopher.

"My palace is a little chamber, thrice my own length; finery never entered it, and neatness never left it. My bed is a mat, and the coverlid a piece of felt; on these I sit by day, and sleep by night. A lamp is on one side, and on the other a pot of perfume. The singing of birds, the rustling of the breeze, the murmuring of a brook, are the only sounds that I hear. My window will shut, and my door open, - but to wise men only; the wicked shun it. I shave not like a priest of Fo; I fast not like the Tao-tsé. Truth dwells in my heart; innocence guides my actions. Without a master, and without a scholar, I waste not my life in dreaming of nothings, and in writing characters, still less in whetting the edge of satire, or in trimming words of praise. I have no views; no projects. Glory has no more charms for me than wealth; and all the pleasures of the world cost me not a single wish. The enjoyment of ease and solitude is my chief concern. Leisure surrounds me, and bustle shuns me. I contemplate the heavens and am fortified. I look on the earth and am comforted. I remain in the world without being in it. One day leads on another, and one year is followed by another; the last will conduct me safe to port, and I shall have lived for myself."

Dramatic entertainments are in China as in Europe closely connected with poetry. The songs and recitative in the lighter pieces, abound with characters of double meaning and equivocal expression; but are generally so contrived, that, while the written characters shall bear one sense, the sound shall convey to the ear another; and these subterfuges are resorted to, in order to avoid that punishment which the magistrates would be compelled to inflict for a breach of the law, respecting public decorum, in the publication or exhibition of any thing directly and unequivocally obscene; and yet real life is represented on the stage without any of its polish or embellishments; all acts, however infamous or horrible, are exhibited on the stage; a murder or an execution. Whether the culprit be condemned to die by the cord, by decollation, by being cut into ten thousand pieces, or by being head alive, the spectators must be indulged with a sight of the operation. Nor do they stop here. Those functions of animal life, over which decency requires a veil to be thrown, are exhibited in full display; many of them so gross and indelicate, so coarse in the dialogue, and so indecent in the scenic representation, that foreigners who have witnessed them have retired from the theatre in disgust.

It is no excuse that these obscene exhibitions were performed for the amusement of foreigners, whom they are pleased to consider as barbarians; the representation of real life, in its ugliest dress and most hateful deformities, could only be con-

China.

ceived by a people of depraved habits and a vicious taste. Of the Court exhibitions, we have amusing descriptions in the Journals of Lord Macartney, Van Braam, and De Guignes. Lord Macartney describes the theatrical entertainments to consist of great variety, tragical as well as comical; some historical, and others of pure fancy, "partly in recitative, partly in singing, and, partly in plain speaking, without any accompaniment of instrumental music, but abounding in battles, murders, and most of the usual incidents of the drama." The grand pantomime followed, the subject of which his Lordship conceived to be "the Marriage of the Ocean and the Earth. The latter exhibited her various riches and productions, dragons, and elephants, and tigers, and eagles, and ostriches, oaks, and pines, and other trees of different kinds. The ocean was not behind hand, but poured forth on the stage the wealth of his dominions under the figures of whales and dolphins, porpoises and leviathans, and other sea monsters, besides ships, rocks, shells, sponges, and corals, all performed by concealed actors, who were quite perfect in their parts, and performed their characters to admiration." These marine and land productions paraded about for a while, when the whale, waddling forward to the front of the stage, took his station opposite to the Emperor's box, and spouted out of his mouth into the pit several tons of water. "This ejaculation," says his Lordship, "was received with the highest applause, and two or three of the great men at my elbow desired me to take particular notice of it, repeating at the same time *Hac, kung lao ' charming, delightful*" After this, they were entertained with tumbling, wire-dancing, and posture-making, and the amusements of the morning concluded with various fireworks, which were much admired for their novelty, neatness, and ingenious contrivance.

The Dutch ambassadors were chiefly entertained by the feats of jugglers and posture-makers, after which was a kind of pantomimic performance, the principal characters of which were men dressed in skins, and going on all-fours, intended to represent wild beasts; after them were a parcel of boys habited like mandarins, who were to hunt these animals. "This extraordinary chase, and the music and the rope-dancing, put the Emperor into such good humour, that he rewarded the performers very liberally, and the ladies behind some Venetian blinds appeared, from their tittering, to be equally well entertained."

An eclipse happened, which kept the emperor and his mandarins the whole day devoutly praying the gods that the moon might not be eaten up by the great dragon that was hovering about her; and the next day a pantomime was performed, exhibiting the battle of the dragon and the moon, and in which two or three hundred priests, bearing lanterns at the end of long sticks, dancing and capering about, sometimes over the plain, and then over chairs and tables, bore no mean part.

The dramatic representation of the Eclipse of the Moon is thus described by De Guignes: "A number of Chinese, placed at the distance of six feet from one another, now entered, bearing two long dia-

gons of silk or paper painted blue, with white scales, and stuffed with lighted lamps. These two dragons, after saluting the emperor with due respect, moved up and down with great composure; when the moon suddenly made her appearance, upon which they began to run after her. The moon, however, fearlessly placed herself between them; and the two dragons, after surveying her for some time, and concluding apparently that she was too large a morsel for them to swallow, judged it prudent to retire, which they did with the same ceremony as they entered. The moon, elated with her triumph, then withdrew with prodigious gravity, a little flushed however with the chase which she had sustained."

It is not easy to reconcile the admission of these puerile absurdities and gross indelicacies on the stage where regular dramas of a higher order exist, and comedians are trained up to perform them, unless it be that their thorough contempt for foreigners induces them to think anything good enough for their entertainment. The dialogue in the regular drama is uttered in a kind of whining recitative, full of querulous cadences, which are drowned generally in a crash of trumpets, symbols, gongs, and the kettle-drum. The passions, as in the Italian opera, are mostly expressed in song. If a fight ensues, each of the combatants sing a stanza, and then fall to, and, during the combat, the instruments of music keep up a most tremendous noise.

Comedians are not much esteemed, if we may judge from the statute against actresses, and yet it is said that Kien-lung's mother was on the stage; since which, the parts of females are performed by eunuchs and boys, the latter of whom are regularly bound apprentices to the trade. Peking is said to have about a hundred different companies, and each company to consist of fifty persons and upwards, composed of speakers, musicians, tumblers, and jugglers, so as to suit all tastes. They live in passage-boats, in which they are conveyed from place to place. There are no regular theatres, but players are hired by the wealthy at so much by the day. They are said to be ready at any moment to perform any play that may be fixed upon, out of a list seldom short of 100. These are the sort of plays performed before their countrymen, and not the trash which they exhibit before foreigners at the Court and at the sea-port town of Canton. The translation of *An Hui in his Old Age*, by Mr Davis, is calculated to give rather a favourable opinion of the Chinese drama. It consists of five regular acts; it has plot and character; the action is simply one, and never stands still. It is deficient in wit, but not in sentiment, and the several characters are well preserved. It is, in short, a story that may commonly occur in a family, thrown into action instead of being merely told, and the catastrophe is quietly and naturally brought about.

Many of their dramas, however, are full of bustle and business, and abound with incident. They are generally representations of real life, and contain sometimes the whole life and adventures of an individual,—some great sovereign, or celebrated general,—a history in fact thrown into action, not unlike that "Lamentable tragedy, mixed full of pleasant mirth,

China. conteyning the life of Cambyzes king of Persia, from the beginning of his kingdom unto his death." The argument of a drama of this kind was found among Mr Wilkinsons's papers. An aged matron and her son (the hero of the piece) being reduced to poverty, are driven to the necessity of asking alms for their support. An officer's daughter, finding them of good parentage and education, gives money to the non, and engages the mother to attend on her. The son hires himself to serve in a tea-house kept by an old woman and her daughter. A rakish young officer, liking the daughter, gains the consent of the old woman to take her into his house, but the girl rejects the offer. He then sends his servants to carry her off by force, but the new servant rescues her. The officer lays an accusation against him; he is carried before a magistrate, who orders him a flogging, and to wear the cangue or wooden collar. Not satisfied with this, the young officer sends out his people with cudgels to beat him to death. Unable, on account of the collar, to reach his mouth, they find the young girl giving him food. His hands, however, being at liberty, he lays about him on all sides, and, by a sudden whirl of his wooden ruff, the corner of it strikes the young officer on the head, and kills him on the spot. The head-man of the street takes him and the young woman into custody, carries them before a magistrate, who releases the young man, but takes the girl of the tea-shop into his own house, from which she is suffered to elope by his wife. The superior magistrate of the district being informed of the death of the young officer, and that the girl of the tea-shop was the chief cause of it, sends an order to the inferior magistrate, who had taken her into his house, to deliver her up; she is nowhere to be found; and, in the greatest dismay, this inferior magistrate orders his servants to go out and seize any woman they meet with, and carry her before the superior magistrate. They find, in a temple, the officer's daughter first-mentioned, with the old woman, who had fled from home on her father being disgraced, and all his goods and family seized. She is hurried away before the magistrate, and (in the supposition of her being the tea-house girl) sentenced to lose her head. Being carried to the place of execution at midnight, she is recognised by the old matron's son, who was among the spectators, and who, by seizing the officer's sword, attacks the executioner, and rescues the young lady; but they are speedily taken, and both ordered for execution; the truth, however, is discovered, and the magistrate who played off the trick suffers in their stead. This superior magistrate, however, falls in love with the lady, and proposes to take her for his first or legitimate wife, and hires the young man for his servant. The lady peremptorily refuses, upon which she is ordered to be beaten by the servants till she lies for dead, and the young man is directed to carry the body and throw it into the river. He lays her on the bank, covers her with his cloak, and goes to buy a coffin, as his last act of gratitude for one who had relieved his mother and himself in their distress. A boat approaching, and finding it a woman, carries her off to serve the Tartar queen in her wars against the Chinese; this same people, it seems, having already carried off the old matron and the young girl

of the tea-shop. Our hero returning, and missing the body, was in great distress. However, he tells his master he has obeyed his commands, who by this time had learned whose daughter he had thus cruelly treated; and, to prevent farther mischief, he engages his new servant (the hero of the piece) to put to death her father; instead of which he reveals the whole to the father, and they concert together and put to death his master. The hero then flies to the wars against the Tartars; and it being the custom (or the Chinese thinking so) for the women to fight, he encounters his own mother, the young lady who relieved her, and the girl of the tea-shop, on which discovery he suffers himself to be taken prisoner by the Tartars, is brought before the queen, who, on hearing the story, sets the three Chinese women at liberty, and commits them to his care. They all return into China; they find the father of the young lady restored to his rank and honours, who bestows his daughter on the hero of the piece; and the other young woman of the tea-shop is provided for by his taking her for a second wife. By the Emperor's patent, he is created a great mandarin, for the service he has performed, receives the suitable habits for himself and his two wives, and the congratulations of all their friends.—(Macartney.—Staunton.—Barrow.—De Guignes.—*Missionary Communications* in Du Halde, Grozier, *Mem. sur le Chinois*, &c.)

As connected with the drama, the state of Chinese music may next be considered. Detestable as Europeans must find the very best of this music, such is the force of habit or prejudice, that the Chinese are as fond of their own as a Highlander of the bagpipe. Their ancient writers ascribe to it all those extraordinary and extravagant effects of softening the manners and promoting civilization, taming wild beasts, moving rocks and stones, and, in short, performing all the wonders which have been related of the strains of Orpheus and the lyre of Amphion. The Shoo-king says, that the Emperor *Chun* considered music as one of the most efficient engines of government, and a test for proving the national character. Confucius was so astounded with one of the old airs, that he could neither eat nor drink, and for three months could think of nothing else. In the book of *Odes*, it is remarked, that, while the Institutes of the empire continue to be observed, and music to be cultivated, China will remain a mighty and invincible nation; and one of the early emperors has this remark: "Would you conquer your enemies without bloodshed, diffuse among them songs set to tender and voluptuous melodies, to soften their minds and enervate their bodies, and then, by sending among them plenty of women, your conquest will be complete."

Dr Burney has well observed, that, the more barbarous the age and the music, the more powerful its effects;

"For still the less they understand
The more they admire the slight of hand."

In China the music is still barbarous enough, whatever the people may be who can admire it. It has neither science nor system; but, from a strange confused account given by Pere Amiot, of the generation and true dimensions of the tones (not one word

China. of which, as he afterwards acknowledges, he could understand), the Abbé Roussier concludes, that, like the music of the Greeks, it appears to be the remaining fragments of a complete system, belonging to a people more ancient than either of them. It will, perhaps, be safer to follow Dr Burney's conclusion, "that, from all the specimens he had seen of Chinese music (and he quotes Dr Lind, who resided some time in China, in support of his opinion), all the melodies of this nation have a very strong analogy to the old Scottish tunes;" that "the Chinese scale is very Scottish;" that "both resemble in their melodies the songs of ancient Greece;" and that, "the music of all three ought to be considered as *natural music*."

The Chinese airs are almost invariably sung in slow movements, generally plaintive, and mostly of a querulous or complaining cast; and they are always accompanied by some stringed instrument in the shape of a guitar. They make use, in singing, of so many shakes, their airs abound with so many half and quarter tones, that they are dull, drawing, and drowsy.

Their gamut consists of five natural notes, which they distinguish by five characters of the language, and two semitones; but they use neither lines nor spaces to note down their music. They, however, write down in succession the characters or notes in a column, as they are played, though it does not appear that they pay any attention in marking the time, the key, the mode of expression, &c. but acquire their airs by dint of labour and imitation. Their gamut for instrumental music is so imperfect, and the keys so inconsistent, wandering from flats to sharps, and the contrary, that they are under the necessity of being steadied and directed by a bell or cymbal. They always play, or endeavour to play, in unison, having no idea of counterpoint and parts in music. The band of Lord Macartney, on this account, afforded them no pleasure, except when it played some simple air, such as "Malbrook," or the national song of "God save the king." Some of their instruments, however, do occasionally rise to the octave in the accompaniment.

The instruments in general use are enumerated in the *Encyclopædia*; but there are many others of a similar kind, differing only in their form and the materials of which they are constructed. The wind instruments are, in general, shrill, harsh, and discordant; the drums, bells, cymbals, and other pulsatory instruments, loud and jarring; and the stringed instruments meagre and jingling. The sweetest instrument is a small organ, made of unequal reeds stuck into the upper surface of a hollow cup of wood, of which there are numbers in this country, but for which Dr Burney tried in vain to adapt a scale. This we believe to be the same *tibia* which that literary coxcomb Isaac Vossius maintained to be superior to all the instruments of modern Europe.

As a favourable specimen of Chinese music, the following national song of *Moo-lee-wha* is here inserted:

China.

This air was played by Lord Amherst's band, and delighted the Chinese more than any other.

It may be added, that the affected gravity of Chinese manners, and their unsocial mode of life, are unfavourable to the cultivation of music, which cannot be expected to arrive even at a state of mediocrity, among a people who rarely assemble together, who take no enjoyment in the amusement of dancing, and whom the loves and the graces have not as yet condescended to visit.

In a country where every kind of luxury is dis- Painting, couraged, and some of them constitutes a crime; where property is so precarious as rarely to descend to three generations; and where the useful only is affected to be considered as valuable, no great progress can be looked for in the fine arts. For the same reason that their poetry is deficient in invention, imagination, and dignity of sentiment, and their music of harmony, the sister art of painting is wanting in all the requisites that are considered to be necessary to form a good picture. Indeed, it could not well be otherwise; as, independent of their contracted ideas, they offend against every principle of perspective which, with the effects produced by a proper disposition of light and shade, they affect to consider unnatural. That it is not from want of talent that their drawings and paintings are so extravagantly outré, is sufficiently proved by the facility and accuracy with which the painters of Canton copy any picture put into their hands, whether on paper, glass, or canvas; and, so far from the Abbé Grozier's Parisian idea being true, that their best works are executed in Peking, the very reverse is the case: all the arts, manufactures, even down to common printing, being worse executed in the capital than in any other city of the empire; and the reason is obvious enough; for the moment that a man acquires a superior reputation, he is summoned to the palace, where, within its spacious precincts, his talents must be exercised for the emperor alone. Here their arts and manufactures remain stationary, while the artists of Canton, being in the habit of copying from better models, are superior to any that the imperial palace can boast. It is all very well for a Chinese to pretend, that the ancients greatly excelled the moderns in the art of painting, and to

China.

produce examples, in their books, of one painter having drawn on the palace walls some hawks so very natural, that the little birds, afraid to approach, flew screaming away; and of another having painted a door on a wall, the deception of which was so complete, that people endeavoured to go through it. But why should the Jesuits repeat these idle stories as if they were facts? Or, why should we be told that the Chinese would be good sculptors if the art was not prohibited by the government? which is so far from being true, that in every temple, bridge, and burying-ground, may be seen all manner of grotesque figures of men, women, quadrupeds, and other creatures, that never existed but in the sculptor's imagination; and these we have abundantly in all manner of materials, wood, stone, metals, and baked clay. Individual objects they can paint with great accuracy; and in a composition each individual object is represented as close to the eye. Thus, the leaves of trees, however distant, are distinctly represented; and objects in the background are painted of the same size with those of the same kind in the foreground, which they absurdly contend to be proper, because they are so in nature. It may be doubted, whether the most skillful European artist can excel a Chinese in painting a bird or a reptile, an insect, a fish, or a flower,—so correct is he to nature, that not one plumula of a feather, nor a single scale of a fish, escapes him, and every shade and tint of colour is minutely imitated. It is strange, that a man of Pauw's sagacity should suffer his judgment to be so warped as to assign the "singular disposition of their optical organs" as the cause which prevented the Chinese from becoming good painters. As little truth is there in his assertion, that they are unable to copy from good models, without falling into their own style, and converting European eyes, ears, and noses, into those of a Chinese; they are the most servile imitators on earth. A Chinese will imitate the likeness of any object in shape, colour, and proportion. Though, when left to himself, he has no mind to convey the idea of distance, solidity, expression, and magnitude of objects, by fore-shortening, perspective, and a due distribution of light and shade, yet he will copy them all in a picture with scrupulous accuracy.

Sculpture.

Sculpture has been thought by some to date its improvements, if not its origin, from monumental edifices. No country can boast a greater number or variety of objects of this nature than China, but, like the rest of its edifices, they are totally destitute of the character of solidity and duration. A few monsters, or distorted forms of men and domestic animals, generally moulded in clay, are sometimes placed among the tombs, but they are wholly undeserving of notice. In cutting wood, in forming the root of a plant into the shape of human beings, quadrupeds, or monsters, they succeed better; and communicate to the features or to the action a high degree of expression; the same things occur in metal and in porcelain; but the human figure is always clothed, and a naked statue never seen. Some of the gigantic clay figures in the temples are by no

China.

means void of character and expression, and the images cut in stone, which sometimes adorn the avenues to the palaces, the gates of cities, and the parapets of bridges, monstrous as they generally are, show that, by proper encouragement and instruction, they are capable of producing something better; but they seem to be deficient in taste and feeling, and to possess no general ideas of the beauties of nature. Content with the representation of individuality, the imagination is never called into play; they servilely imitate what appears before them, with all its beauties and all its blemishes. They are neither deficient in ingenuity or dexterity. They engrave with a tool on copper, on silver, or on wood, as well, generally speaking, as the same kind of work can be executed in any part of Europe; and they are expert enough as lapidaries, in cutting all sorts of precious stones. They use spectacles made of crystal.

It is somewhat remarkable, that a government so long and so firmly established, and a population so numerous and civilized, should, at no period of its history, have constructed a building, public or private, that could deserve the least attention or admiration for its form, solidity, or magnitude, or that could possibly resist the action of two or three centuries; such is the obstinate and inveterate adherence of this people to ancient usage, which has narrowed and confined their ideas in the construction of their dwellings to the primitive tent. Perhaps, however, the want of permanent security to private property may have operated against the construction of solid and expensive edifices, and confined them to the less durable materials of half-burnt bricks, mud, clay, and wood. This is more likely to be the case than the absurd and ridiculous reason assigned by Grozier, that the heat and moisture of the southern provinces, and the rigorous cold of the northern ones, would render buildings of marble and other stone unhealthy and scarcely habitable, and that the same reasons equally operate against a number of stories, as the second and third would not be habitable. If the Abbe Grozier had passed but a single summer's day under the roof of one of the magnificent stone buildings of Calcutta, and another under a Chinese tent, he would not have committed such nonsense to paper. From the want of windows in their houses to the street, and from the small courts behind being barricaded by high walls, which overtop the roofs, and conceal the dwellings from adjoining courts, it may perhaps be concluded that privacy and jealousy of their women, have been the causes that prevent the Chinese from building second and third stories to their dwelling-houses. The Missionaries, however, have assigned the frequent earthquakes in the northern provinces, as the cause of the lowness of the houses and slowness of the materials; as if men would speculate, over a whole empire of unparalleled extent, on a contingency which might never happen, and which, when it had happened, was confined to certain limits. The eruptions of Vesuvius have not prevented the inhabitants of Naples from building palaces, much less the Russians from rebuilding Moscow,—though the distance between these two

China. cities is not greater than that of Pekin, where earthquakes are frequent, to that of Canton, where they never happen.

One can scarcely give credit to the disastrous effects produced by these earthquakes. The lives that have been lost are reckoned in Chinese history by hundreds of thousands, especially under the Mongoo dynasty. This might lead to a suspicion of exaggeration, as famines, earthquakes, and inundations, are considered by the Chinese as the scourges inflicted by heaven on the people, to show its dislike to a sovereign whom it disapproves, did not the accounts of more recent earthquakes given by the Missionaries, who were eye-witnesses of their tremendous effects, correspond with those recorded in Chinese history. It is stated by Pere Mailla, that, in 1679, in the reign of *Kaung-he*, more than 300,000 inhabitants of Pekin were buried under the ruins of the houses thrown down by an earthquake; that, at the same time, above 30,000 persons perished in the city of Tong-tchoo. The statements, however, of the Missionaries are vague and discordant. Pere Couplet says, *Sub decimam horam matutinam, regiam urbem et loca vicina tam horribilis terræ motus concussit, ut innumera palatia, deorum fana, turres et urbis mœnia corruerint; et sub ruinis sepulta quadraginta hominum millia.* Again, in 1730, in the reign of *Yong-tchin*, a violent earthquake shook the capital to its foundations, and 100,000 of its inhabitants were crushed to death. The earth opened in various places, black volumes of smoke issued forth, and left behind large pools of water. The city of Pekin is represented as affording a horrible spectacle; its walls, its palaces, the public buildings, two of the Jesuits' churches, and a multitude of dwelling-houses, were wholly, or in part, thrown down. The palace of the emperor, more solid than any other edifice, was greatly injured; that of *Yuen-min-yuen* was scarcely repairable. Of the 100,000 inhabitants contained in the adjoining village of *Hai-tien*, 20,000 are stated to have perished. The imperial family betook themselves to their barges in the canals, within the precincts of the palace. The emperor distributed many millions of money to the sufferers, and gave the Jesuits one thousand ounces of silver towards the expence of repairing their churches.

If earthquakes were to throw down the tall and ill-built brick pagodas of seven and nine stories in height, there would be nothing surprising; yet these appear to stand the shocks, and many of them are evidently among the oldest buildings in China. These, and the temples of *Fo* and *Tao-tse*, are among the most striking buildings of the country. The want of a national or state religion will best explain the want of those magnificent edifices in China that almost every other civilized nation has reared to the objects of divine worship. Some of their bridges are light, and sufficiently pretty in their appearance; but they are generally slight, and faulty in their construction. They consist of every possible variety of form. Their monuments to the memory of the dead are still more various than their bridges, but they are poor in design and bad in execution. Wooden pillars, forming a triple gate-way, roofed over, and

China. painted, gilt, and varnished, are among the most striking objects that catch the eye of a stranger. They are monuments erected at the public expence, in streets, or by the sides of highways, to commemorate some celebrated warrior, some ancient mandarin, or some antiquated virgin, who had withstood temptation, and never swerved from the strict rules of decorum. To such a one will probably be inscribed in letters of gold, "Honour granted by the Emperor—to icy coldness, hard frost." But these *pei-loos* have little permanency. The mandarin to whom the Emperor's order is addressed for erecting it, employs a carpenter, contracts for building the edifice as cheaply as he can, and pockets the rest of the money. The Emperor's object is answered by publishing the edict in the *National Gazette*. It is handed down to posterity in the great history of the empire, whilst the monument itself in a few years is consumed by the dry rot, and is seen no more.

Superior as the temples and palaces of the Hindus and Mahometans in India and Persia, and indeed throughout Asia, are to those of the Chinese, the dwellings of the latter are infinitely more comfortable in every respect than those of the former. Their stoves for warming the apartments and for cooking, their beds and furniture, bespeak a degree of refinement and comfort unknown to other oriental nations; but the great characteristic difference is, that the Chinese sit on chairs, eat off tables, burn wax candles, and cover the whole body with clothing.

Their naval architecture wears the stamp of great Naval antiquity, and is exceedingly grotesque. They have, in fact, made little progress in maritime navigation, from the inveterate dislike of the government to all foreign intercourse, and to all innovation. The very same kind of vessels as those described by Marco Polo at the port nearest to Pekin, in the thirteenth century, were found without variation by Lord Macartney, five hundred years afterwards, and, accurate to the Italian's description, even to the number of compartments into which the hold of each vessel was divided. They had anchors of wood, and ropes and sails of bamboo. The boats and barges for internal commerce and communication are very varied, generally commodious, especially the passage-boats on the grand canal, and all of them suited to the depth and velocity of the stream, and the width of the locks and floodgates of the respective canals and rivers which they are intended to navigate. These vessels are so numerous as almost to supersede the necessity of land-carriage; and the most common and convenient mode of travelling in China is in barges, which are generally provided with cabins for sleeping, and a kitchen and utensils for cooking victuals. Their military navy is unworthy of the name. It consists of a flotilla, whose principal occupation is that of conveying soldiers where they may be wanted, and looking after pirates and smugglers. An English frigate would beat the whole naval force of China. (Grozier, Du Halde, Barrow, De Guignes, &c.)

The state of their military architecture and military science is equally rude and imperfect. There is nothing, in fact, from the celebrated wall on the

China.

side of northern and western Tartary, to the mouth of the Bocca Tigris near Canton, that merits the name of a fortress. They are all of the same construction, being mounds of earth heaped into the shape of a wall, and cased on each side with bricks, and flanked with square towers at bow-shot distance; and with walls of this description all their cities are surrounded.

Military and Defences.

The best defences of China are its great distance from any civilized country; its rugged mountains and sandy deserts on one side, and a stormy sea, whose navigation is but little known, on the other. In its military strength it can place little or no confidence,—a fact which has frequently been proved by the successful incursions of the Tartars, who have twice since the Christian era conquered the whole country, and changed the ruling dynasty. There is little doubt, indeed, that a well appointed army, of 15,000 or 20,000 men, led by an experienced general, would easily make its way from Canton to Peking. It has been supposed, from their skill in fire-works, and from the frequent mention of them in ancient books, that the deflagrating power of nitre, sulphur, and other ingredients, were well known to them; but it is pretty evident that they had but an imperfect if any knowledge of cannon or musquets, before the arrival of European missionaries in the capital. We may form some notion of the mode of fighting of the Tartars and the Chinese about the Christian era, from the memoir of a general officer, presented to the Sovereign, when about to make war on the Tartars.

“The manner (this general says) in which the Tartars carry on war is very different from ours. To mount up and descend the steepest mountains with astonishing rapidity; to swim deep and rapid rivers; to brave storms of wind and rain, hunger and thirst; to make forced marches, and overleap all impediments, training their horses to tread in the narrowest paths; expert in the use of the bow and arrow, they are always sure of their aim—such are the Tartars. They attack, retreat, rally, with a promptitude and facility peculiar to themselves. In the gorges of the mountains, and in the ravines and deep defiles, they will always have the advantage over us; but on the plains where our chariots can perform their evolutions, our cavalry will always beat theirs. Their bows have not the strength of ours; their spears are not so long; and their arms and arrows are inferior in quality to ours. To stand firm, to come to close quarters, to handle the pike, to present a front, to cut their way when surrounded, are the proper manœuvres of our troops, of which the Tartars are ignorant, and against which they can oppose no successful resistance. In such situations, with equal numbers, our forces are as five, when the Tartars are but as three.” (*Hist. Gen. de la Chine.*)

The first mention of anything like fire-arms, and that is but an equivocal one, is in the year 1219, when Gengis-khan was penetrating the provinces of China. It is stated, that the Chinese, from the turrets of the walls of Tiao-yong, played their machines called *pao* (the present name of guns), by which they killed great numbers at every stroke. Again, when Ogdai-khan laid siege to Lo-yang, the Chinese

commandant Kiang-chin, invented a kind of *pao*, which hurled large stones to the distance of one hundred paces, with such accuracy as to strike any point that might be desired. But another passage is more to the purpose. The Tartars are said to have breached an angle of the wall, by employing more than 100 machines, consisting of tubes, each made of thirteen laths of Bamboo; that the Chinese repaired these breaches with wood, straw mixed with horse dung, &c., which the Tartars set on fire with their *ho-pao* (fire-tubes), and immediately afterwards we find these *ho-pao* called *Tchen-tien-ley* (heaven-shaking thunder); and it is further stated, that a certain substance put into them, when set on fire, explodes like a thunder clap, loud enough to be heard at the distance of a hundred *lee* (30 miles). This description, and that of the effects produced, leave no doubt of these bamboo staves, hooped together, being the first attempt in China at the use of cannon, to which succeeded, probably, those of plates of malleable iron, also hooped together, several of which kind have been found in India, and also seen by Bell lying in heaps, within the walls of a city near the great wall.

In 1453, we find mention made of chariots of war, carrying cannon in their fronts; but, it is probable, they knew very little of the use of them; for when *Chin-ting*, in 1608, made war upon the Tartars on the northern frontier, and was defeated, the Portuguese at Macao, availing themselves of the panic into which the Chinese were thrown, made an offer of assistance with a party of artillery. A Jesuit was dispatched from the capital to hasten the new auxiliaries. The party consisted of 200 Portuguese, and as many Chinese, trained and exercised in the European manner; and they were commanded by two Portuguese Captains, Pierre Cordier, and Antoine Rodriguez del Capo. They were feasted and treated with distinguished honours on their passage to the capital, where they were well received and generally admired, except in the cut of their jackets, which, according to Chinese notions, were too scanty to be elegant. Their admiration, however, soon ceased, and in a few days they were sent back to Macao. It is stated, however, by one of the missionaries, that this was owing to a Portuguese and four Chinese being killed in firing them. That the Jesuit Verbiest taught them how to cast cannon there can be no doubt, for the president of the tribunal of rites thanks the missionaries for this signal service; and the matchlocks now in use by the Chinese troops, are nothing more than the old Portuguese matchlock.

The Tartars are soldiers by profession, mostly cavalry, and their arms, the bow and a broad scimitar, which they wear on the left side, with the point forwards, and which they draw by carrying the right hand behind them, in order (they say) that their adversary may not cut the arm when in the act of drawing. They are arranged under eight banners, distinguished by different colours. The Chinese soldiers are for the most part a sort of militia, enrolled for the defence of the extended frontier, guards to the city gates, the military posts placed at certain distances along the roads, rivers, and canals. All expresses are forwarded from post to post by the soldiers. Vast multitudes are employed to assist the civil magistracy,

China.

China. and act in the cities as police-officers. Their dress and appearance are most military, better suited for the stage than the field of battle,—their paper helmets, padded gowns, quilted petticoats, and clumsy satin boots, are but ill adapted for the purpose of war. Indeed, unless it be to quell an insurrection, or to pursue bands of robbers, the Chinese military are rarely called away from their pacific employments. There was some anxiety, on the return of Lord Amherst through the country, that the military should put on an imposing appearance. "Through the whole route," says the Emperor, "take care that the soldiers have their armour fresh and shining, and their weapons disposed in a commanding style, and that an attitude be maintained at once formidable and dignified."

The people are all enrolled for service, when called upon, from a certain age. A father of a family, having a certain number of children, is exempt from service—an only son, and a son who supports his parents, are both exempt. Great distinctions are shown to those who fall in battle. The body of an officer is burnt, and his ashes, with his armour, and a suitable eulogium, sent to his friends; the bow and sabre of a common soldier slain in fight are sent to his family; rewards are distributed, and honourable mention made of the deceased in the Pekin Gazette.

Since the conquest of Western Tartary, completed by Kien-long, they are not likely to be engaged in any foreign wars. If the neighbouring states, which pay a nominal vassalage, contribute nothing to their wealth or strength, neither are they likely to give them trouble or uneasiness: they have nothing to apprehend on the side of Tartary but an irruption of the Russians, an event which has been supposed not altogether foreign to the plans of the present autocrat of that overgrown empire. (*Hist. Gen. de la Chine concernant les Chinois.*)

Sources.

Nothing has yet appeared in Europe from an authentic source, to warrant any other conclusion than that of the utter ignorance of the Chinese in the pure, speculative, and abstract science of mathematics. Their knowledge of arithmetic and geometry is bounded by mere practical rules. Their numerical notation is marked down by symbols of the language, as that of the Greeks and the Romans was by letters of the alphabet; and, like them, the Chinese symbols want that power of position which the Arabic numbers possess. The common operations of arithmetic are generally performed by a few balls strung on wires, somewhat resembling the Roman abacus, and sometimes by the joints of the fingers. (See ARITHMETIC in this *Supplement*.) The measure of quantity is usually determined by reducing all surfaces and sides to the dimensions of squares or cubes; and with those few practical operations, they contrive to manage all the common purposes of life.

Yet the Chinese have been represented by some of the French missionaries as profound astronomers, at a time when all Europe was in a state of barbarism; as being able to calculate the recurrence of eclipses; to adjust the irregular motions of the sun and moon; to measure the distances of the planets, &c. The ridicu-

lous ceremonies observed by the great officers of state when eclipses happen, furnish, it is true, no proof against the knowledge of their causes. A government established in ancient customs cannot afford to lop off any of its props; and the foretelling of eclipses, the frightening away the dragon that would devour the sun or moon, the favourable or unfavourable omens of the heavenly appearances, are so many engines for keeping the ignorant in awe. The Imperial Calendar is an admirable coadjutor with the Imperial Gazette. But when we find, from their own annals, and from the report of the earliest travellers, that foreigners have had the superintendence of the astronomical part of this almanac, and that, from the defective knowledge of these foreign astronomers, and the occasional want of them altogether, the national calendar, as declared by one of their emperors, had undergone no less than seventy-two revisions, it may safely be concluded that the Chinese know very little of the matter. M. Freret says he had in his possession the copy of a celestial chart, constructed in China about the sixth century of the Christian era, on which were inserted 1460 stars in their proper positions, at least sufficiently near to be recognised, but this may have been made mechanically, and perhaps by a foreigner. It is recorded in their annals, that in 718 of the Christian era, an Indian astronomer of the name of Koo-tan having brought from the west a treatise on astronomy, was employed at court to translate it into the Chinese language; and they also mention that Kub-lai-Khan encouraged learned men to remain in China; and that under his reign an Arab astronomer was employed in rectifying the calendar, and constructing astronomical instruments. Since that time Armenians, Bucharians, Hindoos, Arabs, and Christians, have presided over the Board charged with the construction of the National Almanac, in which the native Chinese took no other part than that of assigning the lucky and unlucky days, what was to be done and what abstained from on those days, &c. When Lord Macartney was in Pekin, a Portuguese, who called himself Bishop of Pekin, a person of no great skill in mathematical knowledge, presided over this Board. Indeed the state in which their calendar was found when Adam Schaal, one of the earliest Jesuits, made his way to Pekin, sufficiently proves their ignorance of astronomical calculations, an intercalary month having been introduced into the wrong year. On making them acquainted with this blunder, all the departments of the state, ordinary and extraordinary, were summoned to sit in judgment on the good father's report, which they voted to be erroneous, and that the ancient system should be continued. They kept, however, the learned Jesuit at Court, and quietly allowed him to set them right. The Emperor Kung-kee, who seems to have entertained no high opinion of his Chinese subjects, brought the Chinese President of the Board of Astronomy to trial, because he could not calculate the length of shadow which a gnomon would throw, but which was immediately done by Father Verbiest. This intelligent Tartar put himself under the tuition of the Jesuits, who made for him a quadrant, translated into the Chinese language a set of logarithm tables,

China.

China which were printed, and a copy of which is now in the library of the Royal Society of London,—a very beautiful specimen of Chinese typography. Kaung-hee carried these tables and his quadrant suspended from his girdle, and when in Tartary is said to have constantly amused himself in taking angles, and measuring the height of mountains.

The Chinese system, if system it can be called, of astronomy, resembles so closely that which remains of the Hindoos, that both must have been derived from the same source. The period or cycle of 60 years, by which their chronology is regulated, the period of 10,800 years, observed by the *Tao-tse*, which is the sum of the first three Hindoo ages, with their intermediate periods, the division of the Zodiac into 12 signs, and also into 28 constellations or habitations of the moon, corresponding with the 28 Hindoo *nacshatras*, are so many proofs of a common origin; and both may perhaps have derived the remains of this science from some third nation, more ancient than either; as the little which both nations do possess, appears to be the remains rather than the elements of the science.

The system of policy which discouraged all intercourse with strangers,—which set no value on foreign commerce and navigation,—which cultivated no language but that of the country, which was unintelligible to other nations, must necessarily have kept the people of China in ignorance of all the rest of the world. China was to them, in fact, the whole world. It appears, however, that, at a very remote period, they had intercourse with Pegu, Siam, Malacca, Hindostan, and several of the Asiatic islands. Two centuries before the Christian era, they had a knowledge of the upper regions of Tartary, and one of their travellers gives an account of an inland sea, into which the rivers running to the westward were received, which could be no other than the Caspian. The great islands of Borneo, Java, Sumatra, and Ceylon, are names easily recognised in their annals, on which great numbers of Chinese are still found, retaining their original language, manners, and government. Captain Sayer, of his Majesty's ship *Leda*, on ascending a river of the western coast of Borneo, came unexpectedly on a colony of Chinese in the interior, consisting of not less than 200,000 or 300,000 persons, all united under one chief or captain; and Mr Raffles says, that, near the same place, it has been calculated that the number of Chinese employed in the gold mines alone, amounts to 32,000 working men.

Their knowledge, however, of their immediate neighbours was very limited and imperfect. By the aid of practical geometry, they had a tolerable notion of their own country. Pere Mailla asserts, that, on comparing the ancient chart of China, said to be copied out of the *Shoo-king*, with the actual survey made by his brother Jesuits and himself, and which took them ten years to complete, they found the limits and the positions of the provinces, the courses of the rivers, and the direction of the mountains, pretty nearly to accord, but the proportions of the objects to each other, and to the whole, were not in the least observed. He further observes, that they saw and gazed with astonishment and admiration at

China. the chasms which the Emperor Yu caused to be cut through solid mountains, to open new channels for the waters of the Yellow River. Some, however, will be apt to conclude that it was the water itself, and not the Emperor Yu, which opened these channels.

Of natural and experimental philosophy, they know only what the Jesuits taught them, and that appears not to be much. Of clock-making, dialling, optics, and electricity, they know nothing; of hydrostatics and hydraulics, very little; they raised water by a machine resembling the Persian wheel, and by a large wheel, with bamboo tubes fixed obliquely on its rim; but they were ignorant even of the principle of the common pump. The use of most of the mechanical powers is known to savages, but the most commodious and effective application of them was not known to the Chinese; in most cases, manual strength supplied the place of mechanical power. When Mr Barrow, in delivering the presents to the Emperor Kien-long, failed in making him comprehend the use of the mechanical powers from a complete set of models, the old man observed, that they might serve as play-things for his grandchildren.

The nature of their own language, their universal State of the ignorance of any other, and their pertinacious resistance to all intercourse with foreigners, may explain the low ebb of the sciences and liberal professions in China. The maxims of the sovereigns and sages of antiquity,—the rites and ceremonies and duties required by the civil and religious institutions of the empire,—the laws and customs,—are the points of knowledge which lead to wealth, power, and distinction in the state. As there is no established religion, so none are paid or preferred by the government for instructing the people; as there is no pleading in criminal or civil suits, so there are none who act as attorneys or advocates; and the practice of physic is attended with too little either of honour or emolument to excite emulation in men of rank and ability in the pursuit of it, and is generally in the hands of the sectarian priests of Fo and Tao-tsé, or of low vulgar quacks. Without the least knowledge of anatomy or surgery, they can know little of the animal economy. The seat of the disease they pretend to discover by the quackery of the pulse, by the eye, the nose, the tongue, the ears, and the voice. When this is ascertained, they prescribe their vomits, purges, febrifuges, &c. extracted from the three kingdoms of nature, of which mercury, antimony, rhubarb, and gin-seng, constitute no inconsiderable part; of gin-seng alone, they profess to have no less than seventy-seven preparations. Their surgery consists chiefly in acupuncture and sham-pooing, and is practised chiefly by the barbers. There are certain persons whose occupation is to discover whether those who may be found dead, have died a natural death or by violence, whether by their own means or that of others, and the verdict of the criminal court is often grounded on the decision of these quacks.

The Emperor Kaung-hee soon convinced himself that several of the Jesuits were better skilled in medicine than his own physician. At first, however,

China. he had some scruples, upon being attacked by a fever, of following their advice. Three of the first physicians to the court, dissuaded him from taking a medicine, of whose qualities they professed themselves ignorant, and advised him to let the disease go on, that they might discover its true character. The emperor, however, at last took the Peruvian bark which the Jesuits had prescribed, and soon recovered; but it is said in the *General History*, that several officers, who had similar fevers, were first ordered to take the bark, and finding it at least harmless, he then ventured upon it himself. As ignorance is a crime in the eyes of the ignorant, it is more especially so at the court of China, and made capital in those to whom the life of the sovereign is entrusted. The three physicians were therefore delivered over to the criminal court, who condemned them to death; but Kaung-hee mitigated the punishment to that of exile, and rewarded the Jesuits with a house in Pekin, and contributed largely towards the building of a church.

Kaung-hee was a man of great humour, and used frequently to joke with the Missionaries respecting their religion and the customs of their country. One day he asked Mezzabarba, the pope's legate, if it was the custom in Europe to condemn a man to death without sufficient proof of his guilt? and being answered in the negative,—“One cannot,” says the emperor, “attach too great a value to the life of man;” and turning to his body physician, and ordering him to approach, “Here,” continues he, “is a much more formidable person than myself; I can only put a man to death on legal proof of guilt, but this fellow can dispatch whomsoever he pleases without the form of trial.”

Whoever may be curious to see the quackery of the pulse detailed, without a complete knowledge of which a physician would gain no reputation in China, may find a translation of the doctrine in the collection of Du Halde.

The Chinese are subject to a species of contagious leprosy, which their physicians cannot cure, and which the law ordains to be a legitimate cause of divorce, as the only means to stop its progress. The itch is most prevalent, and cutaneous disorders of various kinds very common; but they have escaped the plague, more, as Pauw thinks, by constant ventilation,—by burning sandal-wood dust, and other odoriferous woods,—by the abundant use of musk and various strong scented drugs, than by any attention to cleanliness; perhaps, also, the universal smoking of tobacco may have contributed to save them from the horrors of the plague. (*Hist. Gen. de la Chine* par Du Halde.)

Though little progress has been made in any of the liberal arts, or abstract sciences, or little as they are likely to advance under a system of government which interdicts all intercourse with foreign nations, the arts which necessity demands,—which add to the conveniences, and increase the comforts, of a civilized state of society, seem to have flourished at a very early period of their history; and many of them have been brought to a degree of perfection which is still unequalled by the most polished nations of Europe. Whatever depends on mere imitation

China. and manual dexterity, can be executed as well, and as neatly, by a Chinese, as by the most skillful artists of the western world; and some of them in a style of very superior excellence. No people, for example, have carried the art of dyeing, or of extracting dyeing materials from so great a variety of animal, mineral, and vegetable substances, as the Chinese have done; and this merely from a practical knowledge of chemical affinities, without troubling themselves with theories derived from scientific principles. In like manner, practice has taught them how to detect the exact proportion of alloy that may be mixed with gold and silver, and how to separate it. We import from China their native cinnabar, but our vermilion, extracted from it, is not to be compared with theirs for brilliancy and deepness of colour, which is supposed to be given to it by long and patient trituration under water. Again, their beautiful blues on their porcelain are more transparent, deep, and vivid, than the same blues applied to our pottery ware; yet we supply the Chinese with the same cobalt frits from which our own colours are extracted. It has been supposed, that the greater or less brilliancy of the colours used for painting porcelain, depends more on the nature of the glaze on which they are laid, than on their own intrinsic merits. Here, then, we have something still to learn from the Chinese. The biscuit of their porcelain, too, is much superior in whiteness, hardness, and transparency to any which has been made in Europe. The Swansea porcelain comes the nearest to it in these respects, supposed to be owing, in some degree, to a proportion of magnesian earth being mixed with the aluminous and silicious ingredients. In form and decoration, which depend on a taste and feeling which the Chinese are strangers to, we far surpass them.

In the cutting of ivory into fans, baskets, pagodas, nests of nine or more hollow moveable balls, one within the other, beautifully carved, the artists of Europe cannot pretend to vie with the Chinese; yet it does not appear that they practise any other means than that of working in water with small saws. As little can Europeans pretend to rival their large horn lanterns, of several feet in diameter, perfectly transparent in every part, without a flaw or opaque spot, and without a seam; yet a small portable stove or furnace,—an iron boiler, and a pair of common pincers, are all the tools that are required for the manufacture of those extraordinary machines. In silver fillagree they are, at least, equal to the Hindoos, and their lacquered cabinets, and other articles, are excelled only in Japan. They are not less expert in cutting tortoise-shell and mother of pearl, and all kinds of gems and stones. They have a method of ornamenting their cabinet wares, tea-chests, &c. with spangles laid on with the black varnish in the shape of plants, birds, insects, &c. exhibiting varied iridescent colours, appearing like metallic scales that have undergone the process of heat; but they are nothing more than the thin lamina of a particular species of shell (*Helix*) which they have a method of separating by boiling, as they pretend, for the space of half a moon. In all the metals they work with neatness; and if they make not a lock or a hinge

China.

that an English artist would look at, it is only because a Chinese would not pay the price of a good one. Their white copper is a metal, or a mixture of metals, unknown in Europe; and though we think that we have ascertained the component parts of the famous gong to be copper, tin, and bismuth, we are yet unable to make a Chinese gong. In works of the loom, and especially in the manufacture of silk and satin cloths, we cannot pretend to cope with them; and their silken twisted cords, tassels, and all kinds of embroidery, in general the labour of females, are extremely beautiful. In the variety of gums, spices, perfumes, they excel the rest of the world. Our artists can attest the excellence of their ink, and their paper and printing may challenge those of Europe. Many other branches of the mechanical arts might be enumerated, in which the Chinese may consider themselves as second to none, but those already mentioned are sufficient to exemplify their skill in this respect. There are no manufactories carried on by machinery, or on a great scale. Generally speaking, each individual in the country spins, weaves, and dyes his own web. It would appear, however, from some regulations laid down in the *Lou-lee*, that of porcelain, silks, satins, and certain other articles, government is its own manufacturer. The manufactories of porcelain and the coarser kinds of pottery, for the sake of the coal, are mostly in Kiang-see, and the village of Kin-teh-chin, it is said, contains nearly a million of people, all of them engaged in the potteries.

Population.

There is no subject on which the accounts of the missionaries are so vague and contradictory as that of the population; yet they all affect to refer to official documents. They agree, however, in stating it to be something immense, though the highest number is not equal to two-thirds of the enormous mass of 333,000,000, which the Mandarins attendant on Lord Macartney's embassy gave to that nobleman as the amount of the population. The inaccuracy, however, not to say impossibility of that account, is obvious from mere inspection. The numbers in each province are given in round millions, and in two provinces the number of millions is precisely the same. In the *General History of China*, the population is frequently stated at different periods, but in a way so loose and vague as to deserve little attention. There can be no doubt, however, that, from time to time, a census is ordered to be taken, and the result of it is made public; that the number of *mouths* is always included; but that a separate list of the taxable inhabitants only is taken at the same time, and is all perhaps that the government cares about. Thus it is stated, that, under Yang-tee, in the 609th year of the Christian era, the empire contained 8,900,000 families, which, at six to each family, would give a population of 53,400,000; but, to show how very little numbers are to be depended on, it is also stated that China, at that time, was from north to south 14,815 *lee*, and from east to west 9300 *lee*, or 4444 miles by 2730, which is about three times its actual dimensions, at the same time its magnitude.

Again, it is stated that, in the year 1222, under the reign of Hooi-tong, before the Tartar conquest, the Board of taxes ordered a census to be taken which

amounted to 20,882,258 families, and 45,734,784 persons, or about 2½ to each family, which is absurd. In 1290, after the Tartar conquest, Kublai-Khan directed a census to be taken of the taxables. It amounted to 12,196,206 families, comprehending 58,834,711 persons; but it is admitted that the state of the country prevented the whole being taken. In 1502, Shiao-tsung caused a census to be taken, the result of which is stated to have been 53,280,000 mouths. There is a strange difference between these numbers, and those which are published by Grozier, purporting to be a census of all the people in China, taken in the years 1760 and 1761, in the former of which, the list amounts to 196,837,977 mouths; in the latter to 198,214,553, making an increase in one year of 1,376,576 mouths.

If we are to give credit to these accounts, we must suppose that the population of China must have attained its prodigious magnitude within the last two or three centuries, and that it must be greatly on the increase; but we are immediately stopped short from drawing this conclusion, by the translation of some statistical accounts of China by Mr Morrison, taken by order of the present emperor *Kia-king*, to compare with a similar statement made at the commencement of the reigning dynasty. According to this census, the total population, including the twelve Tartar banners, and all ranks and conditions, great and small, amounts to between 145,000,000 and 146,000,000 of mouths; and this account agrees very exactly with that census taken by Kien-lung in the year 1743, and contained in the *Ye-tung-tché*, or *All matters concerning China*, a curious work we have before mentioned. By this census, the number of heads of families paying taxes is stated at 28,514,488; which, by reckoning five persons to each family, would give 142,582,440. The number of the literati, the military, and others exempt from taxation, will amply make up the deficiency. Grozier, indeed, by the omissions of P. Amiot, and the exemptions as above mentioned, swells the total to 157,301,755.

This enormous population is fed and subsisted, and all its wants entirely supplied, from China alone. Except a few English broad cloths and metals, a few furs from Russia, and a little cotton from Bombay, it receives but little external supplies. The extent and fertility of the soil are amply sufficient for its demands. China consists, at least, of one million and a half of square miles, and has about 97 persons to a square mile. Deduct a third for waste lands, lakes, and mountains, and 646,000,000 acres still remain, which give near 4½ acres of land to each individual. The land is subject to an arbitrary tax, generally about one-tenth; and, in order to ascertain the revenue, a report was made to Kien-lung in the year 1745, of the amount of land under cultivation. It was as follows:

	King.
Land in the possession of individuals,	7,081,142
Belonging to the Tartar standards,	13,838
To the military,	259,418
To the sectarian priests,	3,620
To the literary,	1,429
	<hr/> 7,359,447

China.

Resources.

China. Each *king* being 100 *moo*, and a *moo* equal to a superficies whose length is 2400 *tchee* and breadth 10 *tchee*. The *tchee* is about 14.55 English inches; so that the Chinese *moo* is to the English acre as 10,890 to 8821, by which it will be found, that, agreeably with the above statement, the land under cultivation was about 600 millions of acres.

Classes of
Society.

The constituent parts of the population of China were anciently considered to consist of four classes; the *tsé*, or learned, who governed and instructed the rest; the *nung*, or agriculturists, who provided food and materials for clothing the rest; the *kung*, or artisan or manufacturer, who clothed, and built, and furnished houses for the rest; and the *shang*, who distributed and exchanged the productions of the other two among all the classes of society; but nothing like a division into *castes* ever appeared in China. On the contrary, every encouragement is held out for the children of the three inferior classes to aspire to the first.

The numbers of the *tsé*, or officers and literary men, consisting of the members of the several Boards, Governors of provinces and cities, Judges, Treasurers, Collectors, Commissaries, Inspectors, &c. with an enormous list of subaltern officers, according to Grozier, amount to 98,615, and of the literati, who every year take their degrees, and qualify for office, 24,701, the whole of whom living at any one time, cannot, he says, be estimated at less than 494,000. The military officers are also reckoned among the learned, and the number of those who have actual commands amount to 7411, each of whom, on an average, employs nine subaltern officers under him: the whole, therefore, of these would amount to 74,110, and the total of the military or militia is estimated at 822,621; but one of the officers of government told P. Amiot that the military exceeded two millions; and this agrees pretty nearly with the information given to Lord Macartney.

A court kalendar and an army list are published in Peking four times a year, each consisting of several volumes; a tolerable proof of the frequent changes that take place in the subordinate movements of this vast machine.

The great mass of the people, however, are employed in productive labour; perhaps, on a rough estimate, full two-thirds in agriculture and the fisheries; the remaining third, after deducting the military, the civil officers, the students, and candidates for office, amounting, perhaps, on a rough guess, to about ten millions, are manufacturers, tradesmen, shopkeepers, and the multitudes that are employed in the numerous vessels and barges on the rivers and canals to carry on the internal commerce of the kingdom. Agriculture is the productive labour that has always received the highest encouragement from the government, and occasionally the Emperor himself has turned out into the field, with great pomp and solemnity, to hold the plough as an example to the peasantry; perhaps, however, as Pauw observes, if they would remove all the trammels from agriculture, it would have a better effect than the continuance of this ancient ceremony. These trammels are, however, fewer and lighter than in most countries. One-tenth of the estimated produce is all that is required

China. for the state; and they have neither priesthood nor poor to maintain, each family being compelled by law and custom to take care of its poor relations, and the sovereign taking care of the spiritual concerns of his subjects. The monarch may be considered as the universal and exclusive proprietor of the soil; there is no such thing as freeholds; but undisturbed possession is kept so long as the holder complies with the conditions on which the land was granted. As there are no public funds, and capital vested in trade is not very secure, nor the profession highly esteemed, the purchase of land is the most eligible mode of rendering capital productive. Still there are very few great landed proprietors. Two reasons may be assigned for this. First, the rate of legal interest being as high as 3 per cent. for a month, it would be ruinous to borrow money on mortgage; and, secondly, it appears, by the penal code, that the proprietorship of the landholder is of a very qualified nature, and subject to a degree of interference and control, on the part of government, not known under any of the European governments. It can only be disposed of by will under certain restrictions; the inheritors must share it under certain proportions. If a proprietor should neglect to register his land in the public records, and acknowledge himself responsible for the payment of the taxes, such land becomes forfeited. If land, capable of cultivation, be suffered to lie waste through the inability of the proprietor to till it, another may obtain permission to cultivate it; the mortgagee becomes responsible for the payment of the taxes until the land be redeemed by the proprietor. All these restrictions operate against large landed proprietorships.

Much has been said in praise of Chinese agriculture—much more, in fact, than it deserves; in Europe it would be despised. There are no great farms in China; few families cultivate more than is necessary for their own use, and for payment of the imperial taxes; and without teams of any kind; without any knowledge or practice of a succession of crops; without any grazing farms, for feeding cattle, or for the dairy, of which they are totally ignorant, making no use of either milk, butter, or cheese, they can have little manure, nor can the land be kept in good condition. In fact, the old fallowing system is followed, and, in many parts, the spade and the hoe are the great implements of cultivation, their miserable plough scarcely deserving the name. The command of water is the principal substitute for manure. Every substance, however, that can be converted into manure is most carefully collected; and numbers of old people and children of both sexes find employment in scraping together, with wooden rakes, into their little baskets, whatever may have fallen in the streets or roads, where these

"Lend pensioners upon the traveller's tract
Pick up their nauseous dole."—

Leaves, roots, or stems of plants, mud from the sides of canals, and every sort of offal that presents itself, of which human hair, shaven from the scalps of a hundred millions weekly, forms no inconsiderable ingredient, are carefully scraped together. Large earthen vessels are sunk in the ground, to

China.

which, it is said, their cattle are taught to retire ; and on the outskirts of many towns and villages are small buildings, invitingly placed for the accommodation of passengers who may have occasion to use them. All these resources, however, are very limited, and the utmost supply thus afforded can only serve for horticultural purposes.

The whole of the land in China, under cultivation, may be said to be employed exclusively for the subsistence and clothing of man. The staff of life is rice ; and it is the chief article of produce in the middle and southern provinces. This grain requires little or no manure ; age after age the same piece of ground yields its annual crop, and some of them two crops a year. In the culture of rice water answers every purpose ; and nature has supplied this extensive country most abundantly with that valuable element. It is here that Chinese agricultural skill is most displayed ; the contrivances for raising it out of rivers where the banks are high, by means of wheels, long levers, swinging buckets, &c. ; or of leading it down from mountain springs, and along terraces levelled on the sides of hills, or in little channels across the plains, are all admirable ; but when, from long drought, the rivers run low in their channels, and the springs fail, a scarcity of the crop is the inevitable consequence, and the effects of famine are most dreadful ; for though the government has not been wanting in storing up a year's supply of grain in the public magazines (the produce of the taxes paid mostly in kind), yet, before the beneficent intentions of the sovereign can be carried into effect, there are so many previous memorials and references necessary, and so many forms of office to pass through, that the mischief has worked its effects before the remedy is applied ; and, though in this vast empire the scarcity of grain may be local and partial, they have no relief to look to from without, and the system of external commerce is too slow in its operations to throw in a timely supply where it may be most wanted. In the northern provinces, where water is less abundant and less depended on, wheat, barley, buck-wheat, and a great variety of millets, supply the place of rice. Every where are met with leguminous plants of different kinds, pumpkins, melons, sweet potatoes, and whole fields of a luxuriant vegetable called *pei-tsai*, the white herb, apparently a species of brassica, which is salted for winter consumption. In Kiang-nan and Tche-kiang vast tracts of land are planted with the white mulberry tree as food for the silk-worms. They appear like a young orchard of cherry trees, being kept low by constant pruning, to make them throw out young shoots and fresh supplies of leaves. In all the middle provinces are large fields of cotton, which supplies the usual clothing of the great mass of the population, in addition to which, immense quantities are imported annually from Bombay. That peculiar species of a yellowish tinge, which we call Nankin, is not worn by the Chinese, at least in its natural colour ; blue, brown, and black, are the prevailing colours. Patches of indigo are generally found in the vicinity of the cotton plantations.

The tea-plant, which forms so important an article for the common beverage of the country, and also

China.

for exportation, is cultivated only in particular provinces, and in certain situations ; but it is found in gardens and small enclosures in every part of the empire, being very much of the habit and appearance of the broad-leaved myrtle. We scarcely yet know whether the different kinds of tea are from the same plant, or different species of the same genus. The leaf of the sou-chong is broader than that of the hyson, but this seems to constitute the only difference. Both sorts undergo the process of *roasting* in their iron pans ; the black in a higher degree of heat than the green, which is sufficient to give a different character to the extractive matter from the two sorts ; and the nervous quality usually ascribed to green tea, may be owing to the little alteration which the juices of the leaf undergo, from the small degree of heat that is used in the process. To procure the fine flavour, the Chinese usually press the green teas into the chests and cannisters while hot. They have a practice also of giving a finer bloom to dull green teas, by sprinkling a little indigo, mixed with powder of gypsum, while stirring the leaf about in the pan. The different sorts of black and green are not merely from soil, situation, and age of the leaf ; but after winnowing the tea, they are taken up in succession as the leaves fall : those nearest the machine, being the heaviest, is the gun-powder tea ; the light dust the worst, being chiefly used by the lower classes. That which is brought down to Canton undergoes there a second roasting, winnowing, packing, &c., and many hundred women are employed for these purposes ; the rate of pay being about fifty of their small copper coins, or fourpence *per* day. The Chinese say that the best tea is that which is gathered in the morning, while the dew is on. The gathering in the hyson countries, Kiang-nan and Fokien, commences about the middle of April, and continues till about the middle of May. The collecting, the rolling, the twisting, and roasting, give employment to a multitude of people. From the berry of the *tcha-wha*, or flower of tea (*Camelia sesangua*), a fine edible oil is extracted. The almond and the Palma Christi also afford them an oil for culinary purposes. The white wax is the produce of a tree, or rather of a small insect which frequents the tree ; and the *Croton sebiferum* yields an excellent vegetable tallow ; both of these articles serve them to make candles. In the southern provinces, sugar is a common article of cultivation ; but it is rather a luxury than an article of common consumption. It is used mostly in a coarse granulated form ; but for exportation, and for the upper classes, it is reduced to its crystallized state. Tobacco is universally cultivated, and in universal use, by all ages, and both sexes. Fruits of every kind abound, but mostly bad, except the orange and the *lee-tchee*, both of which are probably indigenous. The art of grafting is well known ; but they do not appear to have taken advantage of this knowledge to the improvement of their fruits. They have also an art which enables them to take off bearing branches of fruit, particularly of the orange and peach, and transfer them, in a growing state, to pots, for their artificial rocks, and grottos, and summer-houses. It is simply by removing a ring of the bark, plastering round it a ball

China. of earth, and suspending a vessel of water to drop upon it, until it has thrown out roots into the earth. It would require too much space to describe the various vegetable productions used for food and for clothing,—for medicine, and for the arts. The climate and the soil are well adapted for producing almost all that the rest of the world affords, except, perhaps, those parts which lie within a few degrees of the equator; and the Chinese have obtained their full share even of them.

They are exceedingly sparing in the use of animal food. Those important articles of milk, butter, and cheese, are wholly unknown to them. The broad-tailed sheep are kept in the hilly parts of the country, and brought down to the plains; but the two animals most esteemed, because they contribute most to their own subsistence, and are kept at the cheapest rate, are the hog and the duck. Whole swarms of the latter are kept in large barges, surrounded with projecting stages, covered with coops, for the reception of these birds, which are taught, by the sound of a whistle, to jump into the rivers and canals in search of food, and by another call to return to their lodgings. They are usually hatched by placing their eggs, as the ancient Egyptians were wont to do, in small ovens, or sand-baths, in order that the same female may continue to lay eggs throughout the year, which would not be the case if she had a young brood to attend. The ducks, when killed, are usually split open, salted, and dried in the sun, in which state they afford an excellent relish to rice or other vegetables.

The fisheries are free to all; there are no restrictions on any of the great lakes, the rivers, or canals. The subject is not once mentioned in the *Leu-lee*; but the heavy duties on salt render the use of salt fish in China almost unknown. Besides the net, the line, and the spear, the Chinese have several ingenious methods of catching fish. In the middle parts of the empire, the fishing corviorant, the *Pelicanus piscator*, is almost universally in use; in other parts, they catch them by torch light; and a very common practice is, to place a board painted white along the edge of the boat, which, reflecting the moon's rays into the water, induces the fish to spring towards it, supposing it to be a moving sheet of water, when they fall into the boat.

When animal food fails them, the Chinese make no scruple in eating lizards, toads, grubs, cats, rats, mice, and many other nauseous creatures. The naked Egyptian dog is commonly exposed for sale in the market. But rice, the hog, and the duck, may be considered as the staple articles of human subsistence for the great mass of the population. Those who can afford it indulge in every species of luxury, and more especially in gelatinous soups, which, while they pamper the appetite, are supposed to excite the passions, and to increase their corpulency, which, in their ideas, confers a degree of respectability and dignity to which a small meagre figure can never arrive.

Commerce. No country in the world is better adapted from situation, climate, and products, for extensive commerce, than China; yet no civilized country has profited less by those advantages. The happy distribu-

tion of its numerous rivers, aided by artificial canals, afford an almost uninterrupted water communication from the northern to the southern, and from the western to the eastern extremities of this grand empire; and thus a facility is given for the interchange of the products of one province with those of another, unknown in any other country, and unequalled even in Great Britain. But the commerce that exists is principally that of barter; no system of credit is established between the merchants of distant provinces; no bills of exchange; no circulating medium of any kind, as a common measure of value, excepting a small copper coin, of the value of the thousandth part of 6s. 8d., or about one-third of a farthing. The multitudes of barges of different sorts and sizes, which vary in their construction on almost every river, are incredible. The Chinese are rarely to be trusted where numbers are concerned; but they are probably not far amiss in stating that the number of imperial barges employed in the grand canal and its lateral branches, for the purpose of collecting and distributing among the public granaries the rice and grain paid in kind as taxes, amount to 10,000, or, as they express it, where they mean to be correct, to 9999. A vast number of vessels are also employed in conveying the copper currency from place to place, wherever it may be wanted; others in collecting the silks, cottons, and various articles of taxes, paid in kind, and depositing them in the public magazines; and the salt barges alone are probably not less numerous than those which carry grain. It was calculated that the depot of salt accumulated at Tientsin for the use of the capital and the northern provinces, was sufficient for a year's consumption for thirty millions of people. This was all brought up, in the course of the summer, from the sea-coast of Tche-liang and Fokien, in sea-going vessels. Cakes of coal-dust and turf, for fuel, and cakes made up of various ingredients for garden manure, employ a multitude of barges; and when to these are added the various kinds of vessels employed in general commerce, in the conveyance of passengers and baggage, in breeding ducks, and in the fisheries of the interior, we may be sure that the number of persons who constantly reside upon the water amounts to many millions, and are probably equal to the whole population of Great Britain. It may be doubted if these are included in any census.

All foreign commerce is systematically discouraged. The extent, fertility, and variety of their soil and climate, happily situated between the extremes of heat and cold, partaking of the advantages of both, without experiencing the inconveniences of either, supply the Chinese with the productions of almost all the world besides, whether to minister to the necessities, the comforts, or the luxuries of their numerous population; and leave this great empire, as a nation, completely independent of foreign supplies through the medium of commerce. Satisfied, or affecting to be satisfied, with the prodigal bounty of nature, jealous of strangers, governed by a gradation of arbitrary despotism, the Chinese consider it as a favour bestowed on foreigners to open one of their ports for the interchange of commodities. The revenue derived from this limited intercourse is of little or no

China.

importance at the chief seat of government. The largest estimate that can be made of the value of the whole of foreign commerce, and the largest computation of revenue flowing from it into the imperial treasury, is but as a drop in the ocean. Individual and local interests might and would most materially be affected by any prohibition of an intercourse which has now subsisted for a century and a half; but the government pays little regard to the prosperity or misery of a particular province. The interested views of individuals may, for a time, keep up a trade which is at variance with the general rule of policy prescribed by the laws; and the frequent discussions with the English, whose power they are aware of and dread, will most probably determine them ultimately to close Canton against all foreigners. The English they will not venture particularly to exclude, though they know that other nations would take their articles of produce without forcing upon them European broad cloths, which they affect not to want, but would give them specie, which is, of all other things, what they most desire.

The luxuries, however, which wealth requires, have forced a foreign trade by their own subjects with the nations of the east, as well as with Europe. A very extensive intercourse is carried on by them with Japan, the Phillipine Islands, Java, Sumatra, Timor, Gelolo, and the great island of Borneo, in all of which are found multitudes of Chinese living in habits of peaceful industry, in the midst of the more idle and less civilized natives, conducting the concerns of trade, cultivating the ground, and exercising all the various branches of the mechanical arts; in no place, however, varying in the smallest degree their original character. But though the Chinese spread themselves over every part of the Asiatic, and into many of the Polynesian Islands, there seems to be no reciprocity of commerce by the vessels of those countries visiting the ports of China, excepting some ten or twelve junks that annually visit the southern ports of Fokien from Japan, and perhaps as many from Cochin-China. "From Canton," says Lord Macartney, "to Ten-chou-foo, at the entrance of the Gulf of Pe-tche-lee (to say nothing of the country within the Gulf itself), is an extent of coast of near two thousand miles, indented with innumerable harbours, many of them capable of admitting the largest European ships, and all of them safe and sufficiently deep for the vessels of the country. Every creek or haven has a town or city upon it; the inhabitants, who abound beyond credibility, are mostly of a trafficking mercantile cast, and a great part of them, from their necessary employment in the fishery, which supplies them with a principal article of their subsistence, are accustomed to the sea, and the management of shipping." Yet with all these advantages, all foreign commerce in foreign bottoms is interdicted to these people; whatever they wish to import must be fetched by themselves; and the articles thus brought in are numerous and of considerable value. Thus from Java alone they import birds' nests to the value of half a million dollars annually. The sea slug or biche-da-mar (*holothuria*), from the coast of New Holland, Timor, and adjoining islands, to a still greater extent—sharks' fins from the same quarter—

China.

copper from Japan, and tin from Bantam—pepper, areca nut, spices of different kinds, ebony, sandal wood, red wood for dyeing, tortoise-shell, pearl-shell, coral, camphor, wax, and a variety of articles, generally produced or collected by their own countrymen, resident on the islands of the east.

When Lange, who accompanied Ismaeloff, the Russian ambassador, asked permission for his nation to establish factories in all the provinces, the reply of the Emperor was, "I allow you to remain here (Pekin), and other foreigners at Canton, so long as you and they give me no cause of complaint; but if this should ever be the case, I will neither suffer you to remain here, nor them at Canton;"—so very indifferent does the Court affect to be about foreign commerce. In the whole of this extensive empire, there are but two places where the natives have any intercourse with Europeans,—at Canton with the crews of the several maritime powers, and at Kiackta with the Russians; and this intercourse is chiefly confined at the former to a select number of men, appointed or licensed by the government; at the latter it takes place only under special directions of the government itself, through merchants appointed under the seal of the Emperor. Of the instructions given to these merchants, the Russians procured a copy a few years ago, though the punishment for betraying them is condemnation to track the imperial barges for life; and a more singular document was never issued by any government. It confirms all that has been said of the meanness and knavery of this proud and insolent people; and as it has not before now appeared in print, a summary of it may prove amusing, and may serve to show, at the same time, the notions entertained by the Chinese with regard to the conduct of foreign commerce.

It sets out by stating that the aim of every nation, trading with other countries, is to prevent the advantage being on the side of the foreign nation; to do this the more effectually, and to establish harmony and frankness, "all the letters received by any one of the licensed merchants from their partners, are to be opened in a public assembly, that they may act in concert against the Russians." 2. That as the general principles of commerce require that prices and demands should be foreseen, means must be taken to ascertain what articles the Russians are in want of, and what prices they fetch in Russia; what supplies they may have or expect in the market, and what value they bear in Russia; every one is therefore to strive with all his might to get at this information, and lay it before a general meeting, when the president will give to each merchant a note of the quantities of each article, and of the prices he is to buy at, and of those articles which he is to withhold from the Russians. 3. That the Chinese market is to be kept scantily supplied, and Russian goods not eagerly sought, that the trade may be of importance to them, and the commerce advantageous to China. 4. That care be taken that the quantity of Chinese goods should appear always less than that of the Russians; and that no fresh goods be brought into the market before all the old stock be sold off. 5. That no eagerness be shown, in the purchase of Russian goods, how much soever any in-

division of the merchants may be in want of them, "for the interest of the whole company is not to be sacrificed to that of an individual." 7. That when the Russians have a scanty supply of any article that may be likely to meet with a considerable demand in China, a great eagerness is to be shown to buy up the whole; the Russians are to be told that China is very much in want of the said article, and one merchant is to outbid the other, and, when bought, they are to divide the quantity among themselves. 8. That the Russians, thus tempted by the high prices, and the assurance given them of the great demand, will cause large supplies to be brought to market, when they are to be told that the article is no longer in request in China, &c. and thus the goods will be obtained at a cheap rate from the foreigners, to the great advantage of the whole nation. 9. Whenever the Russian merchants shall attempt to raise the prices of any commodity in consequence of its scarcity, every obstacle must be thrown in their way for the space of a month, and if they will not lower the prices, the whole trade must be suspended, and if, on complaint of the merchants, the Russian Government should interfere, it will not be attended to, and the answer will be, that the commerce between the two nations shall cease. The 10th article contains an impudent falsehood—it instructs them not only to tell the Russians that the quantities of the several articles on hand are much less than they really are, but that "China does not produce silk and cotton." The 11th article directs them to carry on all their intercourse in the Russian language, which every one engaged in the trade must learn in order to prevent the Russians from feeling the necessity of learning the Chinese language, and, by that means, "of discovering the secrets of the trade or those of the government" by overhearing conversations, &c. The 12th directs them to treat the Russians politely; permits reciprocal visits; but forbids a Chinese to pass a night in a Russian house; directs, that in these visits each should endeavour to learn something about the affairs of the Russian Government, and according to the importance of the information obtained, will be the value of the reward. The 13th directs, that a new merchant arriving at Mai-mai-chin, is not to do any business for a whole year, but merely to look on and learn the nature of the trade, "for fear he should, by some mistake, break the thread of the whole." The 14th and 15th prohibit gold and silver, manufactured copper and iron from being exchanged, and the introduction of all articles of luxury, of goods manufactured in China, and of wine and spirituous liquors. 16th, "The secrets of our trade in the interior as well as of that on the spot, must not be revealed, that this indiscretion may not occasion a rise in their prices, and a fall in ours, and thereby injure our empire and the trade of our subjects." The eight remaining articles prescribe the various punishments for disobedience of the foregoing instructions, from a reprimand to that of death. The 22d runs thus: "Whoever betrays to the Russians the secrets of our commerce in the interior, or the prices of Russian products in the interior, or the demand for them, the quantity he holds himself, or that others hold at Kiackta, or that may be on the road thither, shall be banished from Kiackta for ever,

and be sent to the galleys for three years; but whoever betrays to them *these instructions* verbally, or in effect, or by deed, shall be sent to the galleys for life." And by the 23d, "Whoever betrays the secrets of the government which are not to be known by the Russians, shall be beheaded, not, however, without the sanction of the Emperor." We know very little of the value of the trade carried on at this place in this extraordinary manner. It consists chiefly in exchange, on the part of Russia, of fur and various peltry, horses, drugs, &c. for tea, silks, nankeens, porcelain, lacquered ware, and other small articles similar to those imported by England. (From a Russian MS.)

The principal mart for foreign commerce is that of Canton, the only port, in fact, which is open for foreigners. For the last twenty years the foreign commerce of this port was almost exclusively in the hands of the English and the Americans. The English commerce consisted of two distinct branches; the one direct from England, and a complete monopoly of the East India Company; the other indirectly carried on by individuals from the several presidencies of India, chiefly from Bombay. The Chinese system of conducting their foreign trade at Canton, is somewhat different from that of Kiackta. It is a monopoly confided to a certain number of persons known by the name of Hong merchants; *hong* being the name of the large factories or masses of buildings surrounding square courts similar to our old inns, or the caravanseras of the East. Each nation has its separate hong, and the whole being arranged along the bank of a fine river, with a broad quay in their front, their appearance has a grand effect from the opposite side. The river is at least as broad as the Thames at London, and for the distance of four or five miles it is crowded by Chinese vessels of all descriptions, which, from the multitude of people constantly residing in them, may be considered as a floating city. Foreign vessels are not allowed to approach nearer to Canton than Whampoo, which is about fifteen miles down the river.

The Chinese levy no specific duties on the articles imported, nor *ad valorem* duties on the cargoes; the only impost is on the ship itself, and is estimated by a rule as absurd as it is partial and unequal. They measure the length from the centre of the foremast to the centre of the mizen-mast; and the breadth is taken close abaft the main-mast. The length is then multiplied by the breadth, and the product, divided by ten, gives the measurement of the ship. All ships, according to this measurement, are classed under first, second, or third rates; all other vessels, however small, are classed as third rates. By this rule a ship of 100 tons would pay from 4000 to 5000 dollars, and a ship of 1000 not above ~~that~~ that sum.

When a ship arrives at Canton, she is immediately consigned to one of the hong merchants, who is responsible to the government for the good conduct of her commander and crew during her stay in the river. Through his hands all her cargo must pass, and by him the return cargo must be supplied. By long experience of the honourable manner in which the servants of the East India Company conduct their concerns, a degree of mutual confidence has

China—been established, which is unknown even in Europe. Not a bale of cloth, nor a package of any kind, is ever opened to be examined, but is received and passed from hand to hand, the company's mark being a sufficient guarantee of its answering the description in the invoice; the same confidence prevails on our part; and though the Chinese attach no dishonour to roguery in trade, few packages of teas, silks, nankeens, or other articles, are received in England which are not conformable with the samples. This, however, was not the case originally, nor is it so yet in purchases made by individuals; but as the hong merchants take back any article not answering to the description given of it, and return it to the person who supplied the same, the inducement to cheat the Company is taken away. Some of the hong merchants accumulate fortunes which, for their magnitude, are unknown in Europe; others become bankrupt, in which case, as they are all appointed by government, the rest find it expedient to compound with their creditors, and, by such arrangements as may mutually be agreed upon, undertake to liquidate, by instalments, the whole debt. At the close of every season there is generally a balance in the hands of the hong merchants due to the East India Company, from half a million to a million Sterling, and as much more due to individuals trading on their own bottoms. The hong merchants plead the necessity of retaining this balance, in order to enable them to make advances to the tea growers, silk and cotton manufacturers, &c. who, as in India, are persons of small capitals, and require these advances to raise their respective products.

The articles exported by the East India Company consist of broad cloth, long cloths, camblets, furs, lead, tin, copper, &c. but the chief article is broad cloth, the annual export of which at this time is not far short of one million Sterling; the amount of the remainder may be L.200,000 or L.300,000. The commanders and officers of the Company's ships have the privilege of taking out certain articles, such as peltry, glass, clocks, watches, cutlery, coral, prints, and paintings, &c. to the amount of about L.200,000.

The principal article of import from China is tea. Of this article England alone takes from 24,000,000 to 30,000,000 pounds weight annually. The rest of the cargo consists of nankeens and raw silk. The minor articles of porcelain, lacquered and ivory goods, tutanague, mother of pearl, drugs, cinnabar, &c. are chiefly confined to the private trade. The cost and charges of the total imports in the Company's ships from Canton amount to about L.3,300,000, and the sales amount to about L.4,200,000. The continuance of the China trade is therefore of the utmost importance not only to the East India Company, but to the nation at large. It enables the East India Company to pay its dividends, without which, in its trading capacity, it must immediately become bankrupt; it pays into the revenue at least L.3,500,000 annually; it employs about 20,000 tons of shipping, and 2000 seamen: and it supplies an article of consumption which no other part of the world can supply, and which has now become an article of almost universal use; and it takes off one of

the staple commodities of England, to the value of nearly L.1,000,000 Sterling. For many years the balance of trade with England was greatly in favour of China, and required large sums of specie to be sent out annually; but towards the conclusion of the war, when it was most difficult to be procured, when it was most wanted at home, and when its value was greatly increased, England most fortunately drew through India a balance in bullion from China: and thus the Indian commerce with the port of Canton became of the utmost importance to the mother country, as well as to the resident merchants of that distant possession of the East India Company.

The commerce of India with China is chiefly carried on from the two presidencies of Bombay and Calcutta; and it has been stated that the most moderate estimate of the value of tonnage and merchandise necessary for the present extent of this trade is upwards of L.2,200,000 Sterling, exclusive of pearls, sandal-wood, peckhuck, and other inferior articles; and of the pepper, betel nut, rattans, &c. from the east coast and the islands. Bombay is most favourably situated by its geographical position for carrying on an active commerce, and for the employment of a numerous population. The cotton of Guzzerat and the neighbouring countries supplies all that China can take, and a surplus for England; and the imports from China are conveniently distributed along the shores of the Persian and Arabian Gulfs, the northern ports of Guzzerat, and the dominions of the Peishwa. Of late years, the balance in favour of India was drawn from China in the shape of bullion. About three years ago, when, from some misunderstanding with the Chinese, the servants of the East India Company found it expedient to stop the trade of the country ships till the impediments thrown in the way of the direct trade should have been removed, the merchants of Bombay sent a memorial to the Board of Control, and a petition to the House of Commons (neither of which, however, were presented), in which the capital and tonnage embarked in the China trade is thus stated:

Annual Export of Cotton.

	Rupees.
Sent by individuals, at least 100,000 bales or 50,000 cundies, of 784 pounds each. In measurement, 4 bales or 2 cundies are equal to 1 ton; so that, for the cotton alone, 25,000 tons of shipping are required, the value of which is	50,00,000
The average price of cotton on board ship, is not less than 140 rupees per cundy, and the value is	70,00,000
The charges of transit to China, at 40 rupees per cundy, is	20,00,000
Of the quantity of opium annually sold at the Company's sales in Calcutta, at least 2500 chests may be assumed as the quantity exported to China in British ships, which, at 1700 rupees per chest, amounts to	42,50,000
Making a total value of	rupees 1,82,50,000

China.

China. The Chinese appear to have no regular established system of credit among themselves, and the only circulating medium in the shape of coin, is a small piece of base metal (copper, tin, or lead mixed), of the value of the one-thousandth part of six shillings and eightpence, of little more intrinsic value, in fact, than a cowrie shell, which the Chinese, as well as the Hindoos, would seem once to have used; as the same character in their language which signifies a shell signifies also money and wealth; and it enters into the composition of characters which represent *buying, selling, paying, &c.* Silver in small ingots is used in commerce, but they have no determinate value, the price fluctuating with the demand, as in other articles of commerce. The high rate of interest operates as a discouragement to mercantile speculations, and the rigour of corporal punishment is added with the view, as it would appear, of deterring the most hardy speculator. The law says, "whoever shall lend either money or goods, shall only receive three parts in the hundred *per month*," and that "how much soever may be suffered to accumulate, the capital shall remain the same." It is lent from month to month, and if the lender should complain of the interest not being punctually paid, the borrower is subject to the punishment of ten stripes of the bamboo the first month, twenty the second, and so on. While this exorbitant rate of interest, and the penalties attached to the law of usury, operate against all speculation among the Chinese, the Europeans, resident at Canton, have availed themselves of the opportunity of increasing their fortunes at the expence of the Hong merchants, and at the risk of losing both capital and interest. (*From various MS. papers.*)

General appearance of the Country.

When an European first sets his foot in China, he will find the appearance of the country, the buildings, and the people, so totally different from any thing he had before seen, that he might fancy himself to be transported into a new world. In the long line of internal navigation between the capital and Canton, of 1200 miles, with but one short interruption, he will observe every variety of surface, but disposed in a very remarkable manner in great masses; for many days he will see nothing but one uniform extended plain, without the smallest variety; again, for as many days, he will be hemmed in between precipitous mountains of the same naked character, and as unvaried in their appearance as the plains; and, lastly, a ten or twelve days sail among lakes, swamps, and morasses, will complete the catalogue of monotonous uniformity; but whether he crosses the dry plains of Petcheli and Shantung, abounding with cotton and all the varieties of grain and pulse,—the more varied surface of Kiang-nan, fertile in silk, in yellow cotton, in fruits, in the staple commodity of grain, and in every thing that constitutes the luxuries, the comforts, and the necessities of the people,—the dreary swamps, morasses, and extensive lakes of the northern part of Kiang-see, where men subsist by fishing,—or its naked and picturesque mountains to the southward, famous for its porcelain manufactories,—or whether he descend to the fertile plains of Quan-tung, on which almost all the vegetable products of the East

may be said to be concentrated, the grand characteristic feature is still the same—a redundant population. Every where he meets with large masses of people, but mostly of one sex; thousands of men in a single group, without a single woman mixing among them,—men whose long gowns and petticoats give them the appearance of the softer sex, while these are sparingly seen at a distance in the background, peeping over the mud-walls, or partially hid behind trees or bushes; whose short jackets and trousers would make them pass for men among strangers, if their braided hair, stuck full of flowers, and their little cramped and bandaged feet, did not betray their sex. He will be pleased with the unequivocal marks of good humour which prevail in every crowd, uninterrupted and unconcerned by the bawling of some unhappy victim suffering under the lash of magisterial correction; and he will be amused at the awkward corrections of the softer sex to hobble out of sight, when taken by surprise; but his slumbers will be interrupted on the nights of the full moon by the nocturnal orgies of squibs and crackers, gongs and trumpets, and other accompaniments of boisterous mirth.

A constant succession of large villages, towns, and cities, with high walls, lofty gates, and more lofty pagodas, large navigable rivers, communicating by artificial canals, both crowded with barges for passengers, and barks for burden, as different from each other, in every river and every canal, as they are all different from any thing of the kind in the rest of the world,—will present to the traveller an animated picture of activity, industry, and commerce. He will behold, in the lakes and morasses, every little islet crowned with villages and mud hovels. He will observe birds (the *leu-tse*, or cormorant) catching fish; and men in the water, with jars on their heads, fishing for birds. He will see shoals of ducks issuing from floating habitations, obedient to the sound of a whistle; carts on the land, driven by the wind; and barges on the water, moving by wheels, like those recently invented in Europe for propelling the steam-boats. Among other strange objects, he will observe, at every ten or twelve miles, small military guard-houses, with a few soldiers fantastically dressed in paper helmets and quilted petticoats, making use of the fan, if the weather be warm, and falling on their knees, if an officer of rank should pass them.

He will observe that the meanest hut, with walls of clay, and a roof of thatch, is built on the same plan, and of the same shape, with the palace of the viceroy, constructed of blue bricks, and its tiled roof supported on pillars. He will notice that the luxury of glass is wanting in the windows of both; and that, while one admits a free passage to the air, the other but imperfectly resists the weather, and as imperfectly admits the light, whether through oiled paper, silk gauze, pearl shell, or horn.

Nothing, perhaps, will more forcibly arrest the attention of the traveller than the general nakedness of the country as to trees and hedge-rows, of which the latter have no existence, and the former exist only in clumps near the dwellings of the public officers, or the temples of Fo, or Tao-tse. No green meadows will meet his eye; no cattle enliven the

China.

scene; the only herbage is on the narrow ridges which divide the plots of grain, or the brown fallow, as in the common fields of England. The terraced hills he will probably observe to be terminated with a clump of trees, or a pagoda,—the only objects in the distance that catch the eye. But the bridges on the canals, of every variety of shape,—circular, elliptical, horse-shoe, gothic,—slight and unstable as they are, are objects that, by their novelty and variety, must attract notice; and the monumental architecture, which adorns the cemeteries under every form, from the lowly tent-shaped dwelling to the loftiest column,—the elevated terraces, supported by semicircular walls,—and the round hillocks, which, in their graduated size, point out that of the father, the mother, and the children, according to seniority,—are among the most interesting objects that China affords.

If, by chance, he should be admitted within the gates of one of their great cities, as Pekin, Nankin, Sau-tcheou-foo, Hang-tcheou-foo, or Canton, he may fancy himself, from the low houses with curved overhanging roofs, uninterrupted by a single chimney, the pillars, poles, flags, and streamers, to have got into the midst of a large encampment. The glitter arising from the gilding, the varnishing, and the painting, in vivid colours, that adorn the front of the shops,—and, in particular, the gaily painted lanterns of horn, muslin, silk, and paper,—the busy multitude all in motion, and all of one sex,—the painted and gilded inscriptions that, in announcing the articles dealt in, assure the passengers that “they don’t cheat here,”—the confused noise of tinkers, cobblers, and blacksmiths, in their little portable workshops,—the buying, selling, bartering, and bawling, of different wares,—the processions of men carrying home their new-married wives, with a long train of presents, and squalling and noisy music; or carrying to the grave some deceased relation, with most lamentable howlings,—the mirth and bursts of laughter occasioned by jugglers, conjurors, mountebanks, quack-doctors, musicians, and comedians; in the midst of all which is constantly heard a strange twanging noise from the barbers’ tweezers, like the jarring sound of a cracked Jew’s harp,—the magistrates and officers, attended by their lictors, and a numerous retinue, bearing flags, umbrellas, painted lanterns, and other strange insignia of their rank and office;—all these present to the eyes and ears of a stranger a novel and interesting spectacle. The noise and bustle of this busy multitude commence with day-light, and cease only with the setting of the sun; after which, scarcely a whisper is heard, and the streets are entirely deserted.

Towards the central parts of China, near to the places where the two great rivers, the Whang-ho and the Yang-tse-kiang, intersect the Grand canal, a scene, magnificent beyond description, will arrest the attention of the traveller; here he will find himself in the midst of bustle and business. The multitude of ships of war, of commerce, of convenience, and of pleasure, some gliding down the stream towards the sea, others working against it by sails, oars, or wheels, and others lying at anchor; the banks on either side, as well as those of the canals,

China.

covered with towns as far as the eye can reach; the continuance along the canals of cities, towns, and villages, almost without interruption,—the vast number of light stone bridges, of one, two, and three arches,—the temples occurring in frequent succession, with their double and triple tiers of roofs,—the Pei-los, or triple gateways, in commemoration of some honest man or chaste virgin,—the face of the surrounding country, beautifully diversified with hill and dale, and every part of it in the highest state of cultivation,—the apparent happy condition of the numerous inhabitants, indicated by their cheerful looks and substantial clothing, chiefly in silk,—such are the scenes which presented themselves to our countrymen who composed the embassy of the Earl of Macartney, and were recently repeated to those who accompanied Lord Amherst.

He would probably be mistaken, however, in inferring the general happy state of the people, or beautiful appearance of the country, from what might occur along this great line of communication between the northern and southern extremities of the empire. The Dutch embassy setting out in winter, when the canals were frozen, proceeded by a different route, and the inconveniences they suffered, as described by Van Braam, and in a MS. *Journal* in our possession, are such as can scarcely be credited to have occurred in any nation removed but a few degrees from the savage state: The face of the country was dreary, without a visible trace of cultivation, or a hovel of any kind, for the space of eight or ten miles together. In many parts the surface was covered with water, and the mud hovels completely melted down. Very few cities, towns, or villages, occurred in their route, and those were almost universally in a ruinous condition. Near to the capital they passed a city exhibiting only a mass of ruins. It was not before they had crossed the Yellow River that the prints of wheel-carriages marked out the road. The people every where appeared indigent and oppressed, equally destitute of the feelings of humanity and of hospitality. The Dutch were carried in small bamboo chairs, each having four bearers, so weak and tottering that they could seldom go through the day’s journey; and it frequently happened that they halted in the middle of a cold night, in an open uninhabited part of the country, exposed to all the inclemency of the weather, without a hovel of any kind to afford them shelter; and when they reached the end of the day’s journey, the lodgings appropriated for their reception were so miserable, admitting, on all sides, the wind, rain, or snow, that they generally preferred taking a little rest in their bamboo chairs. They observed on the road old men and young women travelling in wheel-barrows, sometimes in litters or chairs carried by a couple of asses, one being fixed between the poles before and one behind. The rivers were without bridges, and crossed, when not fordable, by rafts of bamboo.—All this is corroborated in a subsequent publication of *Voyage à Peking*, by M. de Guignes; and hence it may be concluded, that China, like other countries, has its fertile and its desolate districts, and that much information is yet required to form a competent no-

China.

tion of the real state and condition of this mighty empire.—(Staunton's *Authentic Account*.—Lord Macartney's *Journal*.—Barrow's *Travels*.—*Voyage à Pékin*.—Van Braam's *Journal*.—MS. *Journal*.)

Ornamental Gardens.

One thing, at least, is quite certain, that a traveller in the best and most frequented parts would look in vain for the least trace of those enchanting gardens of which Sir William Chambers and his friend, Lepqua, the painter of Canton, aided by another brother of the brush, Frere Attiret, Jesuit and painter to the Emperor of China, have put together so fanciful a description. Sir William saw, what Europeans generally see in Canton, the shops in China-street, the quay, on which the foreign factories are situated, and, perhaps, a small mean garden, at the head of the first reach of the river, to which strangers are permitted, as a great favour, to go and buy parcels of lettuce and turnip seeds neatly packed up and sold as rare and curious flowers, and the French Jesuit's taste and accuracy may be estimated from his own statement, that "the face of the country from Canton to Pekin is very indifferent, and though six or seven hundred leagues (it is four hundred) nothing occurs worthy of attention." He tells us, it is true, that he was shut up in a kind of close cage, which they laboured to persuade him was a litter, and that he arrived in Pekin without having seen any thing at all on the journey.

With the exception of the imperial gardens of Gehol and Yuen-min-yuen, there is not, perhaps, in all China a piece of ornamental ground of the extent of three acres, and a traveller may pass the whole distance in the open air, which Frere Attiret did in his cage, without seeing a single one of any extent. If he should chance to get a peep within the enclosing walls of those lodges set apart for the residence of the Emperor when he travels, or of the habitation of some magistrate or wealthy merchant, he will probably find a square court of a rood or two of ground behind the women's apartments, concealed completely from public view, in which two or three little fish ponds have their margins fantastically broken by shaped masses of rock, or cut so as to resemble rugged mountains in miniature, among which, planted in concealed earthen vessels, are dwarfish trees proportioned in size to the pigmy mountains, and bearing all the marks of venerable age, causing new roots to strike in old branches, twisting and bending them into particular forms and directions, wounding the stem, and smearing it with sugar to attract the ants and other insects. Among these rocks are narrow paths almost impassable, with holes and crevices here and there to peep through, just to catch a glimpse of some piece of stagnant water, on the shore of which is a wooden temple, a bridge, a pavilion, or perhaps to view a remarkable piece of rock. Within the water, if large enough, an island with its pagoda will probably be placed, or, as occupying less space, the imitation of a passage boat stuck upon piles, and fitted up with appropriate apartments, kitchen, &c. In the recesses of the rocks are seats or small summer houses, opposite to which are parterres of various flowers growing in sunken pots, which can thus be replaced by others in bloom, according to the season of the year; and where there is space, the

China.

peach, the orange, the Lee-tehee, and other fruit trees, are introduced. From the boundary wall, a roof is generally projected, supported on wooden pillars, which forms a covered gallery to walk in; gravel walks are out of the question, and would be wholly inconsistent with the feelings and usage of a nation, the women of which, for whose recreation these gardens are chiefly designed, cannot walk, and whose male population, of the upper ranks, are too indolent to walk. In short, where secrecy is so desirable, where enjoyments are stolen, and walking is considered as drudgery, seats and concealed recesses are best suited to the comfort and the convenience of the people. If a Chinese acts on any principle, it is that of producing the greatest possible variety in the least possible space. He is indebted to nature for many of the most beautiful shrubs and flowers which she has bestowed on man for the gratification of the sense of sight or smell. Various species of camellia, peonia, chrysanthemum, asters, roses, and a numerous list of the choicest flowers, gratify the eye, while the *Pergularia odoratissima*, the *Olea fragrans*, the *Petroselinum Chinense*, and the Arabian jessamine, spread their fragrance around. The sacred Nelumbium breaks the surface of the water with its peltate leaves and showy flowers, and the elegant bamboo, and the water cypress (*Cupressus pendula*), like the weeping willow, give concealment to their seats of retirement, whether for ease or sensuality.

Throughout this extensive empire, embracing so great a variety of climate, the physical and moral characters of the people remain as fixed and unchangeable as the laws and customs, from which, in fact, they receive their colour. Such is the force of ancient usage and the dread of innovation, that a Chinese never stops to inquire what he ought to do on any pressing emergency, but what Yao and Chun did in a similar case four thousand years ago. Time, in fact, may be said to stand still in China. Here not only the system of morals, of social intercourse, of jurisprudence, of government, is the same now as it was three thousand years ago, but the cut of their robes, their houses and furniture, are precisely the same, so that if custom has exercised its dominion over this singular people, they have at least been freed from the tyranny of fashion. Here a young lady may safely wear the head-dress of her great-grandmother, without the imputation of being singular or old fashioned. One of the Missionaries observes, *Parcourez l'empire de la Chine, tout vous semblera fondé dans le même creuset, et façonné par le même moule*. No fault can be found with the metal or the mould in which it is cast. The general stature of the Chinese is about that which, in Europe, we call the middle size, few tall men are to be found among them, few dwarfs and deformed persons, but they are distinguished by many physical peculiarities, as the narrow, elongated, half-closed eye, the lunar and highly arched eye brow, the broad root of the nose; the projection of the upper jaw a little beyond the lower, the thin straggling beard, and the body generally free from hair; a high conical head and triangular face, and these are the peculiar characteristics which obtained for them

General View of Customs and Character

China.

in the *Systema Naturæ* of Linnæus, a place among the varieties of the species distinguished by the name of *homines monstrosi*.

Every individual, without exception, plait his strong black hair into a long tail, something like the lash of a whip, extending below the waist, sometimes to the calf of the leg: this tail grows from the crown of the head, the rest of the scalp being closely shaven; the hair of the beard is pulled out till nearly the age of forty, when its growth is encouraged, and being an indication of age, is considered as a mark of respect. The great mass of the people is decently and substantially clothed; the upper and middle classes in rich silks, satins, and fine cottons, the lower orders generally in cottons; but they are not cleanly in their persons; having, apparently, a particular aversion from cold water, which they never use in its pure state as a beverage, and always warm it for washing the hands and face, even in the middle of the dog-days; yet they use ice in the northern provinces for cooling their fruits.

The countenance of a Chinese man has something in it peculiarly pleasing and good humoured, which is just the reverse with that of the women, at least with those in the common rank of life, the only women who are seen in public. A Chinese is only out of humour when disturbed at his meal; necessity only, not even his own self-interest, will prevail on him to leave his rice unfinished.

The common people seldom sit down to table, nor, in fine weather, take their meals within doors; but each with his bowl in his hand, squatting himself down on his haunches round the boiler, eats his frugal repast of rice or other vegetables, seasoned with a little pork or fish; or salted duck, with oil, fat, or a little soy; washing it down with weak tea, or warm rice beer; or *seau-tcheou*, a villanous ardent spirit. Rice is the staff of life in China, of which they eat largely, but in drinking they are extremely moderate. They are not nice in their choice of food,—dogs, cats, rats, and almost every animal being eagerly sought after by the poorer class. In such a mass of population, many families must necessarily struggle with all the ills of extreme poverty; fewer, however, it would appear, in proportion to the population, than in most other countries; the small imposts on agricultural produce, the easy terms on which land is procured, the small divisions into which it is partitioned out, the multitude of large rivers, lakes, and canals abounding with fish, the freedom of the fisheries, and the extremely moderate rate at which the agricultural and labouring poor are taxed, are so many spurs to industry; and when a man through age or infirmity becomes incapable of labour, his relations are compelled to contribute to his support; a refusal would be an offence against parental affection, which is not in China a mere moral maxim, but carried with it the force of a positive law: poor houses are consequently scarcely known, and beggars exist only in the persons of the priests of Fo and Tao-tse and other impostors, in the shape of astrologers and fortune-tellers. Old age is here highly respected, and the imperial family takes every occasion to set the ex-

China.

ample. On Yung-chin's marriage with a Tartar princess, she distributed a piece of cotton cloth and two measures of rice to every woman throughout the empire whose age exceeded 70 years. In the province of *Shan-tung* alone, whose population may amount to 20,000,000, the list consisted of 98,222 above 70; 40,893 above 80; and 3453 above 90 years of age.

In all ranks of life, but more especially among the magistrates and officers of government, vivacity and activity are less esteemed than sedateness and deliberation; gravity is considered as the test of wisdom, and silence of discretion. A magistrate should never attempt to joke, and should forbear to talk; he should resemble great bells which seldom strike, and full vessels which give little sound. He should never show his anger, as this would put the person who had offended him on his guard. A Chinese of education is a complete machine; he must act and speak and walk abroad, dress, receive and return visits, according to rule founded on ancient usage; the observance of which is a most important part of his duty. If two persons meet, they know from the button on the bonnet their respective ranks, and that alone determines what each has to do and to say. If two officers of equal rank pass each other, they fold their hands and salute each other till out of sight; if of different ranks, the chair or carriage of the inferior must stop while that of the superior passes, and where the difference is very great, the inferior must alight. It is not, as in Europe, that one person may pass another with indifference, may take off his hat or keep it on, may give or refuse his hand, according to the humour in which he may happen to be; if one of the people should fail to pay the respect that is due to their superiors, a few strokes of the bamboo will bring him back to a sense of his duty. Where there is so much ceremony, there must be much hypocrisy and little cordiality.

When one officer pays a visit to another, a sheet of red paper, folded in a particular manner, bearing the name and quality of the visitor, is dispatched before him, that the person visited may know where to receive him, at the gate, in the first court, or in the inner apartment. The card is accompanied by a list of presents meant to be offered. If part be received, a letter of thanks, and a list of those returned, is sent back, with this observation in two characters, "they are pearls, I dare not touch them," in allusion to the prohibition of pearls being worn by any except the Imperial family, or those who have special leave. The visits of an inferior must always be made before the first meal, that the fumes of meat or wine may not offend the person visited. If he means to decline the visit, the bearer of the card is desired to say to his master, that he will not give him the trouble to alight from his chair; but if he does not return the visit in person, he sends his card within three days, and there the visiting acquaintance ends. Where a visitor is received, a prodigious deal of bowing and ceremony takes place. When once seated, to lounge on the chair, to lean back, to sit cross-legged, or to throw about the arms, or to look round, would

China. be a gross breach of good manners. A cup of tea, sipped simultaneously, according to rule, finishes the formal visit.

These restraints of ceremony, imposed more or less on all conditions of men, are incompatible with frankness and sincerity, and beget that want of confidence between colleagues in office, which is particularly observable in this jealous government, by the constant plotting against and undermining each other. The habitual gravity which a magistrate must put on in public, stamps an air of importance on matters of the most trifling nature, though it is said they sometimes relax in private, where they indulge in all manner of excesses, and the stiff formality which strongly characterizes this people, is said to give way, on such occasions, to conviviality; not, however, unless they are well acquainted with their guests. At such feasts, women never appear, but are usually left to be amused by a set of players. To convince the guests how anxious the entertainer is to see them, the invitation is repeated three several times, the first on the preceding evening, the second on the morning of the day, and the third when dinner is ready for serving up, which is the latter of the two meals, and generally from four to six o'clock, according to the season of the year. The guests do not sit down at one table, but generally in pairs at small square tables, every one of which is served precisely with the same kind of dishes, which are very numerous. Besides the ordinary quadrupeds, birds and fishes, used as food, several gelatinous articles, as bears' paws, the hoofs of various animals, stags' sinews, sharks' fins, birds' nests, biche da mer, fucus or sea weed, enrich their soups. With these and other substances mixed with spices, and soys and various herbs, they have an endless preparation of dishes, served up in small porcelain bowls, eaten with porcelain spoons, and two little ivory or ebony sticks, with which they take the pieces of meat or dry rice, and throw them into the mouth. Pastry and sweetmeats are served up at intervals; tea follows the dinner, after which comes the desert. Those who, from illness or accident, send an excuse, have their portion of the dinner sent to their homes. Each guest, the next morning, sends a billet of thanks for the good fare he enjoyed the preceding evening.

Though there are tea houses and cook-shops to which tradesmen, artisans, and the peasantry, with the inferior officers of state and clerks of the departments, occasionally resort to refresh themselves, and to read the Pekin Gazette, there are no promiscuous assemblies or fixed meetings, as fairs for the lower classes, or routes, balls, or music parties for the higher ranks. Dancing is utterly unknown. The clumsy boots of one sex, and the crippled feet of the other, would be ill adapted for the amusement of dancing, even were the sexes permitted to mix together, but "tripping on the light fantastic toe" would not become that gravity which is so essential in the exterior of Chinese good breeding. In the former Tartar dynasty, some Lamas from Thibet brought with them to Court a set of dancing girls, whose lascivious movements gave great offence to the grave and virtuous Chinese, whose general conduct towards the women is nearly as bad as that which prevails among savage tribes. One may

China. discover in their proverbs the feeling toward the sex. "A family," it is said, "in which there are five women, has nothing to fear from robbers; its poverty will protect it." Again, "When the hen crows in the morning, domestic affairs are not going on as they should be,"—and, "What the women have lost in their feet, they have added to their tongues."

It is remarkable enough that the accurate Marco Polo is wholly silent on the subject of the crippled feet of the Chinese women, which there can be no doubt were as common in his time as they are now. Of the origin of this unnatural custom, the Chinese relate twenty different accounts, all equally absurd. Europeans suppose it to have originated in the jealousy of the men, determined, says Pauthier in his severe manner, to keep them "si étroit qu'on ne peut comparer l'exactitude avec laquelle on les garde, qu'à la sévérité avec laquelle on les gouverne." Whatever may have been the cause, the continuance may more easily be explained—as long as the men will marry none but such as have crippled feet, crippled feet must for ever remain in fashion among Chinese ladies. It is kept up by the pride of superiority and the dread of degradation, like the custom of widows burning themselves in India.

The little value set upon females leads but too frequently to that unnatural crime, female infanticide and exposure. There can be no question as to its existence; the extent of it, however, may have been exaggerated. In the Pekin Gazette of 1815 is a representation from a humane magistrate of Kiang-nan to the tribunal of justice in the capital, praying that the horrible practice of selling and putting away wives, and drowning female infants, may be prohibited: on which the emperor Kia-king sagaciously observes, that "the existence of male and female is essential to the continuance of the human species,"—that "husband and wife form one of the five relationships in which human beings stand to each other,"—that "divorce is not allowable, except for one of the seven causes,"—and concludes, "if it be true that it is a common practice among poor families to drown their female infants, and the husband and wife separate for every trifle, these are indeed wicked practices, which should be put a stop to by admonitory and prohibitory edicts." The magistrates of a district of Fokien sent a case to court on another occasion to know how they should act. It was this: A man had made a vow, that if his wife recovered from a fit of sickness, he would make a sacrifice of his son, who was three years of age. The wife recovered, and he performed his vow. The supreme court decreed, that, having violated the laws of nature, he had incurred the penalty of death; but, on a mistaken notion that, by the unnatural sacrifice, he had saved the life of the mother, the emperor mitigated the punishment to 100 blows of the bamboo, and perpetual banishment.

This is but a miserable picture of the state of society in China. It is rendered still worse by the common practice of all oriental nations, which admits of a man taking as many wives as he can maintain. In China, a second or inferior wife is taken without any ceremony, and generally purchased, the children by her are considered as the children of the first wife, and strictly

China.

legitimate; but the mother is without consideration in the eye of the law, and may be disposed of in the same way as she was procured.

The athletic exercises of wrestling, boxing, fencing, the active amusements, such as cricket, golf, bowls, tennis, are wholly unknown, and the sports of the field, as hunting, shooting, angling, as pursuits of pleasure, cannot be conceived by them. The Tartars, however, are fond of hunting, of the pleasures of which the Chinese had so little idea, that Kien-lung, in his *Eloge de Manchu*, seems to think it necessary to acquaint them with the benefits arising from this diversion. Having described the pleasures and the dangers of the chase, "Thus," says he, "ends this delightful and highly useful exercise, which is at once propitious to heaven, to the earth, and to the army; to heaven, by the offerings it affords in its honour; to the earth, which it relieves from the cruel and pernicious guests that prey upon it; and to the army, by accustoming them to the dangers and fatigues of war."

To appear with the head uncovered, and without boots, would be an act of rudeness not to be tolerated. To receive a present with one hand would be equally rude and disrespectful; to mention the word *death* would be an insufferable rudeness. When a person dies, he is said to be gone to his ancestors. Many other peculiarities might be mentioned, in which they differ from the rest of the world, and many in which they resemble the Turks in a very marked manner; but this is the less surprising, as the Turks are from the same Scythian stock.

Suicide is no crime with the Chinese. It is a favour to a condemned criminal to allow him to be his own executioner. Women, and officers of the government, are most addicted to the practice of suicide; the former, perhaps, from a sense of degradation, or in the gloom of solitude; the latter possibly to escape torture or disgrace, when suspected of criminal conduct.

There are two favourable traits in the Chinese character which should not be overlooked—the respect and veneration of children for their parents, and the almost universal sobriety that prevails in all ranks and conditions of men. A curious story is told by Le Gentil, which he had from P. Laureati, respecting the Emperor Kaung-he, who, one day, determined to experience the unknown pleasure of getting drunk. He chose his favourite minister as his bottle companion, who contrived to keep sober while his master was unable to stand. The minister apprized the chief eunuch of the emperor's situation, and hinted that if they did not contrive to cure him of the practice, none of their lives would be safe for a moment—"you must, therefore," he continues, "load me with chains, and throw me into a dungeon." Kaung-he, on waking, inquired for his companion; the eunuch said that he was in confinement by his orders, for having incurred his displeasure. The emperor doubted his senses, but, having ordered the minister to be brought before him, he was so shocked and provoked, that he never afterwards ventured to repeat the experiment.

Like other nations, therefore, the Chinese character has its bright as well as its dark side, and, if we find the latter to be the most prominent, it should be re-

China.

membered that it is drawn chiefly by foreigners, and principally by those whose communication is rare and restricted, or by those who have only visited one of their out-ports, distant many hundred leagues from the seat of government. Here, by all accounts, they are so much given to knavery and cheating, that it is held to be no crime in the seller to cheat, where the buyer is stupid enough to be cheated. Pauw observes, that the shopkeepers would never have thought of writing upon their signs, "here nobody will be cheated," if they had not predetermined to cheat all the world; yet our own shopkeepers are not backward in announcing their "genuine" articles. It is to be feared, however, that the boasted morality of the Chinese is built on no principle of feeling or propriety of action between man and man; and that, where public decorum is not offended, there is no breach of moral duty. Great crimes are not common, but little vices pervade all ranks of society. A Chinese is cold, cunning, and distrustful; always ready to take advantage of those he has to deal with; extremely covetous and deceitful; quarrelsome, vindictive, but timid and dastardly. A Chinese in office is a strange compound of insolence and meanness. All ranks and conditions have a total disregard for truth; from the emperor downwards, the most palpable falsehoods are proclaimed with unblushing effrontery to answer a political, an interested, or an exculpatory purpose. The present emperor asserted, and several great officers of state repeated the assertion, to Lord Amherst, that they saw Lord Macartney go through the whole of their odious ceremony, and that he performed it to admiration.

These are among the dark shades of the Chinese character, opposed to which may be set his sober and industrious habits,—submissive disposition,—a mild and affable manner,—an exactness and punctuality in all which he undertakes to perform; and if he has not been taught a general philanthropy, or if sentiments of love for the whole species have not been instilled into his mind, he has at least the merit of believing in the God of his fathers,—in obeying the commands of his superiors,—and of honouring his father and mother. Under a better government the Chinese could not fail to become a better people; as it is, some favourable traits may be found, both in the habits of the people and the principles of the government. "Some very considerable and positive moral and political advantages," as Sir George Staunton observes, "are attributable to the system of early and universal marriage; to the sacred regard that is habitually paid to the ties of kindred; to the sobriety, industry, and even intelligence of the lower classes; to the almost total absence of feudal rights and privileges; to the equitable distribution of landed property; to the natural incapacity and indisposition of the government and people to an indulgence in ambitious projects and foreign conquests; and, lastly, to a system of penal laws, if not the most just and equitable, at least the most comprehensive, uniform, and suited to the genius of the people for whom it is designed, perhaps of any that ever existed;"—and with this qualified character we dismiss the subject.

CHIVALRY.

Chivalry. THE primitive sense of this well known word, derived from the French *Chevalier*, signifies merely cavalry, or a body of soldiers serving on horseback; and has been used in that general acceptation by the best of our poets, ancient and modern, from Milton to Thomas Campbell.

But the present article respects the peculiar meaning given to the word in modern Europe, as applied to the order of knighthood, established in almost all her kingdoms during the middle ages, and the laws, rules, and customs, by which it was governed. Those laws and customs have long been antiquated, but their effects may still be traced in European manners; and, excepting only the change which flowed from the introduction of the Christian religion, we know no cause which has produced such general and permanent difference betwixt the ancients and moderns as that which has arisen out of the institution of chivalry. In attempting to treat this curious and important subject, rather as philosophers than as antiquaries, we cannot, however, avoid going at some length into the history and origin of the institution.

Origin of
the Institution.

From the time that cavalry becomes used in war, the horseman who furnished and supported a charger arises, in all countries, into a person of superior importance to the mere foot soldier. The apparent difficulty of the art of training and managing in the field of battle an animal so spirited and active, gave the *πρόδρομος ἑκτός*, or *Domitor equi*, in rude ages, a character of superior gallantry, while the necessary expence attending this mode of service attested his superior wealth. In various military nations, therefore, we find that horsemen are distinguished as an order in the state, and need only appeal to the *equites* of ancient Rome as a body interposed betwixt the senate and the people; or to the laws of the conquerors of New Spain, which assigned a double portion of spoil to the soldier who fought on horseback, in support of a proposition in itself very obvious. But, in the middle ages, the distinction ascribed to soldiers serving on horseback assumed a very peculiar and imposing character. They were not merely respected on account of their wealth or military skill, but were bound together by an union of a very peculiar character, which monarchs were ambitious to share with the poorest of their subjects, and governed by laws directed to enhance, into enthusiasm, the military spirit and the sense of personal honour associated with it. The aspirants to this dignity were not permitted to assume the sacred character of knighthood until after a long and severe probation, during which they practised, as acolytes, the virtues necessary to the order of chivalry. Knighthood was the goal to which the ambition of every noble youth turned, and to support its honours, which (in theory at least) could only be conferred on the gallant, the modest, and the virtuous, it was necessary he should spend a certain time in a subordinate situation, attendant upon some knight of eminence, observing the conduct of his master, as what must in future be the model of his own, and practising the virtues of

humility, modesty, and temperance, until called upon to display those of an higher order.

Chivalry.

The general practice of assigning some precise period when youths should be admitted into the society of the manhood of their tribe, and considered as entitled to use the privileges of that more mature class, is common to many primitive nations. The custom, also, of marking the transition from the one state to the other, by some peculiar formality and personal ceremonial, seems so very natural, that it is quite unnecessary to multiply instances, or crowd our pages with the barbarous names of the nations by whom it has been adopted. In the general and abstract definition of Chivalry, whether as comprising a body of men whose military service was on horseback, and who were invested with peculiar honours and privileges, or with reference to the mode and period in which these distinctions and privileges were conferred, there is nothing either original or exclusively proper to our Gothic ancestors. It was in the singular tenets of Chivalry,—in the exalted, enthusiastic, and almost sanctimonious ideas connected with its duties,—in the singular balance which its institutions offered against the evils of the rude ages in which it arose, that we are to seek those peculiarities which render it so worthy of our attention.

The original institution of Chivalry has been often traced to the custom of the German tribes recorded by Tacitus. "All business," says the historian, "whether public or private, is transacted by the citizens under arms. But it is not the custom that any one shall assume the military dress or weapons without the approbation of the state. For this purpose, one of the chief leaders, or the father or nearest relation of the youthful candidate, introduces him into the assembly, and confers on him publicly a buckler and javelin. These arms form the dress proper to manhood, and are the first honour conferred on youth. Before he receives them, the young man is but a member of his own family, but after this ceremony he becomes a part of the state itself." (*Germania* Taciti.) The records of the northern nations, though we cannot rely upon their authenticity with the same unlimited confidence, because we conceive most of the legends relating to them have been written at a much later period than the times in which the scene is laid, may be referred to in confirmation of the Roman historians. The Scandinavian legends and *Sagas* are full of the deeds of those warriors whom they termed heroes or champions, and who appear to have been formed into an order somewhat resembling that of Chivalry, and certainly followed the principal and most characteristic employment of its profession; wandering from court to court, and from shore to shore, bound on high adventure, and seeking with equal readiness their fortunes in love and in war. It would not be difficult to deduce from this very early period some of those peculiar habits and customs, which, brought by the Gothic conquerors into the provinces of the divided empire of Rome, subsisted and became

Chivalry. ingrafted upon the institutions of Chivalry. Tacitus, for example, informs us, that among the Germans, and especially among the Catti, every youthful champion permitted his beard and hair to grow, and did not shave them until he had performed some signal feat of arms. In the like manner, as the general reader may have learned from that irrefragable authority, Don Quixote de la Mancha, a knight who received his order, was obliged to wear white armour and a shield without a device, until, by some daring and distinguished achievement, he had acquired title to an honourable badge of distinction. If this correspondence of customs shall be thought too far fetched and too general, the next, which we also derive from Tacitus, is too close to be disputed. The German warriors who piqued themselves upon this bravery, used, at the commencement of a war, to assume an iron ring, after the fashion of a shackle, upon their arm, which they did not remove until they had slain an enemy. The reader may be pleased to peruse the following instance of a similar custom from the French romance of *Jehan de Saintré*, written in the year 1459, and supposed to be founded, in a great measure, upon real incidents.* The hero, with nine companions at arms, four of whom were knights and five squires, vowed to carry a helmet of a particular shape, that of the knights having a visor of gold, and that of the squires a visor of silver. Thus armed, they were to travel from court to court for the space of three years, defying the like number of knights and squires, wherever they came, to support the beauty of their mistresses with sword and lance. The emblems of their enterprise were chained to their left shoulders, nor could they be delivered of them until their vow was honourably accomplished. Their release took place at the court of the Emperor of Germany, after a solemn tournament, and was celebrated with much triumph. In like manner, in the same romance, a Polish knight, called the Seigneur de Loiselench, is described as appearing at the court of Paris wearing a light gold chain attached to his wrist and ankle in token of a vow, which emblem of bondage he had sworn to wear for five years, until he should find some knight or squire without reproach, by encountering with whom he might be delivered (such was the phrase) of his vow and enterprise. Lord Herbert of Cherbury mentions, in his memoirs, that when he was made Knight of the Bath, a tassel of silken cordage was attached to the mantle of the order, which, doubtless, had originally the same signification as the shackle worn by the German champion. The rule was, however, so far relaxed, that the knot was unloosed so soon as a lady of rank gaged her word that the new Knight of the Bath would do honour to the order; and Lord Herbert, whose punctilious temper at great store

by the niceties of chivalrous ceremony, fails not to record, with becoming gratitude, the name of the honourable dame who became his security on this important occasion.

Chivalry.

Other instances might be pointed out, in which the ancient customs of the Gothic tribes may be traced in the history of chivalry; but the above are enough to prove that the seeds of that singular institution existed in the German forests, though they did not come to maturity until the destruction of the Roman empire, and the establishment of the modern states of Europe upon its ruins.

Having thus given a general view of the origin of chivalry, we will, I. briefly notice the causes from which it drew its peculiar characters, and the circumstances in which it differs so widely from the martial character as it existed, either among the ancient Greeks and Romans, or in other countries and nations. II. We will attempt a general abstract of its institutions. III. The rise and progress of chivalry,—its effects upon the political state of Europe,—and its decay and extinction, will close the article.

I. Agreeably to this general division, the general nature and spirit of the institution of chivalry falls first, under our consideration.

In every age and country valour is held in esteem, and the more rude the period and the place, the greater respect is paid to boldness of enterprise and success in battle. But it was peculiar to the institution of Chivalry, to blend military valour with the strongest passions which actuate the human mind, the feelings of devotion and those of love. The Greeks and Romans fought for liberty or for conquest, and the knights of the middle ages for God and for their ladies. Loyalty to their sovereigns was a duty also incumbent upon these warriors, but although a powerful motive, and by which they often appear to have been strongly actuated, it entered less warmly into the composition of the chivalrous principle than the two preceding causes. Of patriotism, considered as a distinct predilection to the interests of one kingdom, we find comparatively few traces in the institutions of knighthood. But the love of personal freedom, and the obligation to maintain and defend it in the persons of others as in their own, was a duty particularly incumbent on those who attained the honour of chivalry. Generosity, gallantry, and an unblemished reputation, were no less necessary ingredients in the character of a perfect knight. He was not called upon simply to practise these virtues when opportunity offered, but to be sedulous and unwearied in searching for the means of exercising them, and to push them without hesitation to the brink of extravagance, or even beyond it. Founded on principles so pure, the order of chivalry could not, in the abstract at least, but occa-

Peculiar Nature and Spirit of this Institution.

* We may here observe, once for all, that we have no hesitation in quoting the romances of chivalry as good evidence of the laws and customs of knighthood. The authors, like the painters of the period, invented nothing, but copying the manners of the age in which they lived, transferred them without doubt or scruple to the period and personages of whom they treated. But the romance of *Jehan de Saintré* is still more authentic evidence, as it is supposed to contain no small measure of fact, though disguised and distorted. Probably the achievements of the Polish knights may have been a real incident.

Chivalry. sion a pleasing, though a romantic developement of the energies of human nature. But as, in actual practice, every institution becomes deteriorated and degraded, we have too much occasion to remark, that the devotion of the knights often degenerated into superstition,—their love into licentiousness,—their spirit of loyalty or of freedom into tyranny and turmoil,—their generosity and gallantry into hair-brained madness and absurdity.

We have mentioned devotion as a principal feature in the character of chivalry. At what remote period the forms of chivalry were first blended with those of the Christian religion, would be a long and difficult inquiry. The religion which breathes nothing but love to our neighbour and forgiveness of injuries, was not, in its primitive purity, easily transferable into the warlike and military institutions of the Goths, the Franks, and the Saxons. At its first infusion, it appeared to soften the character of the people among whom it was introduced so much, as to render them less warlike than their heathen neighbours. Thus the pagan Danes ravaged England when inhabited by the Christian Saxons,—the heathen Normans conquered Neustria from the Franks,—the converted Goths were subdued by the sword of the heathen Huns,—the Visigoths of Spain fell before the Saracens. But the tide soon turned. As the necessity of military talent and courage became evident, the Christian religion was used by its ministers (justly and wisely so far as respected self-defence) as an additional spur to the temper of the valiant. Those books of the Old Testament which Ulphilas declined to translate, because they afforded too much fuel for the military zeal of the ancient Goths, were now commented upon to animate the sinking courage of their descendants. Victory and glory on earth, and a happy immortality after death, were promised to those champions who should distinguish themselves in battle against the infidels. And who shall blame the preachers who held such language, when it is remembered that the Saracens had at one time nearly possessed themselves of Aquitaine, and that but for the successful valour of Charles Martel, Pepin, and Charlemagne, the crescent might have dispossessed the cross of the fairest portion of Europe. The fervent sentiments of devotion which direct men's eyes toward heaven, were then justly invoked to unite with those which are most valuable on earth,—the love of our country and its liberties.

But the Romish clergy, who have in all ages possessed the wisdom of serpents, if they sometimes have fallen short of the simplicity of doves, saw the advantage of converting this temporary zeal, which animated the warriors of their creed against the invading infidels, into a permanent union of principles, which should blend the ceremonies of religious worship with the military establishment of the ancient Goths and Germans. The admission of the noble youth to the practice of arms was no longer a mere military ceremony, where the sword or javelin was delivered to him in presence of the prince or elders of his tribe; it became a religious rite, sanctified by the forms of the church which he was in future to defend. The novice had to watch his arms in

Chivalry. a church or chapel, or at least on hallowed ground, the night before he had received the honour of knighthood. He was made to assume a white dress, in imitation of the Neophytes of the church. Fast and confession were added to vigils, and the purification of the bath was imposed on the military acolyte, in imitation of the initiatory rite of Christianity; and he was attended by godfathers, who became security for his performing his military vows, as sponsors had formerly appeared for him at baptism. In all points of ceremonial, the investiture of chivalry was brought to resemble, as nearly as possible, the administration of the sacraments of the church. The ceremony itself was performed, where circumstances would admit, in a church or cathedral, and the weapons with which the young warrior was invested were previously blessed by the priest. The oath of chivalry bound the knight to defend the rights of the holy church, to respect religious persons and institutions, and to obey the precepts of the gospel. Nay, more, so intimate was the union betwixt chivalry and religion supposed to be, that the several gradations of the former were seriously considered as parallel to those of the church, and the knight was supposed to resemble the bishop in rank, duties, and privileges. At what period this complete infusion of religious ceremonial into an order purely military first commenced, and when it became complete and perfect, would be a curious but a difficult subject of investigation. Down to the reign of Charlemagne, and somewhat lower, the investiture was of a nature purely civil; but long before the time of the crusades, it had assumed the religious character we have described.

The effect which this union of religious and military zeal was like to produce in every other case save that of defensive war, could not but be unfavourable to the purity of the former. The knight, whose profession was war, being solemnly enlisted in the service of the gospel of peace, regarded infidels and heretics of every description as the enemies whom, as God's own soldier, he was called upon to attack and slay wherever he could meet with them, without demanding or waiting for any other cause of quarrel than the difference of religious faith. The duties of morality were indeed formally imposed on him by the oath of his order, as well as that of defending the church, and extirpating heresy and misbelief. But, in all ages, it has been usual for men to compound with their consciences for breaches of the moral code of religion, by a double proportion of zeal for its abstract doctrines. In the middle ages, this course might be pursued on system; for the church allowed an exploit done on the infidels as a merit which might obliterate the guilt of the most atrocious crimes.

The genius alike of the age and of the order tended to render the zeal of the professors of chivalry fierce, burning, and intolerant. If an infidel, says a great authority, impugn the doctrines of the Christian faith before a churchman, he should reply to him by argument; but a knight should render no other reason to the infidel than six inches of his falchion thrust into his accursed bowels. Even courtesy, and the respect due to ladies of high degree, gave way

Chivalry. when they chanced to be infidels. The renowned Sir Bevis of Hamptoun, being invited by the fair princess Josiane to come to her bower, replies to the paymims who brought the message,

"I will ne gon one foot on ground
For to speke with an heathen bound;
Unchristen houndes, I rede ye flee,
Or I your hearte's bloode will see."

This intemperate zeal for religion the knights were expected to maintain at every risk, however imminent. Like the early Christians, they were prohibited from acquiescing, even by silence, in the rites of idolatry, although death should be the consequence of their interrupting them. In the fine romance of *Huon of Bourdenux*, that champion is represented as having failed in duty to God and his faith, because he had professed himself a Saracen for the temporary purpose of obtaining entrance into the palace of the Amial Gaudifer. "And when Sir Huon passed the third gate, he remembered him of the lie he had spoken to obtain entrance into the first. Alas! said the knight, what but destruction can betide one who has so foully falsified and denied his faith towards him who has done so much for me!" His mode of repentance was truly chivalrous. When he came to the gate of the last interior inclosure of the castle, he said to the warder, "Pagan, accursed be thou of God, open the gate." When he entered the hall where the pagan monarch was seated in full state, he struck off, without ceremony, the head of the pagan lord who sat next in rank to him, exclaiming at the same time with a loud voice, "God; thou hast given me grace well to commence my emprise; may our Redeemer grant me to bring it to an honourable conclusion." Many such passages might be quoted to show the nature of the zeal which was supposed to actuate a Christian knight. But it is needless to ransack works of fiction for this purpose. The real history of the crusades, founded on the spirit of chivalry, and on the restless and intolerant zeal which was blended by the churchmen with this military establishment, are an authentic and fatal proof of the same facts. The hair-brained and adventurous character of these enterprises, not less than the promised pardons, indulgences, and remissions of the church, rendered them dear to the warriors of the middle ages; the idea of reestablishing the Christian religion in the Holy Land, and wresting the tomb of Christ from the infidels, made kings, princes, and nobles, blind to its hazards; and they rushed, army after army, to Palestine, in the true spirit of chivalry, whose faithful professors felt themselves the rather called upon to undertake an adventure from the peculiar dangers which surrounded it, and the numbers who had fallen in previous attempts.

It was after the conquest of the Holy Land that the union between temporal and spiritual chivalry (for such was the term sometimes given to monastic institutions) became perfect; by the institution of the two celebrated military orders of monks, the Knights Templars and Knights of St John of Jerusalem, who, renouncing (at least in terms) the pomp, power, and pleasures of the world, and taking upon them-

selves the monastic vows of celibacy, purity, and obedience, did not cease to remain soldiers, and directed their whole energy against the Saracens. The history of these orders will be found in its proper place in this work; but their existence is here noticed as illustrating our general proposition concerning the union of devotion and chivalry. A few general remarks will close this part of the subject.

The obvious danger of teaching a military body to consider themselves as missionaries of religion, and bound to spread its doctrines, is, that they are sure to employ in its service their swords and lances. The end is held to sanctify the means, and the slaughter of thousands of infidels is regarded as an indifferent, or rather as a meritorious action, providing it may occasion the conversion of the remnant, or the peopling their land with professors of a purer faith. The wars of Charlemagne in Saxony, the massacres of the Albigenses in the south of France, the long-continued wars of Palestine, all served to illustrate the dangers resulting from the doctrine which inculcated religion not as a check upon the horrors and crimes of war, but as itself its most proper and legitimate cause. The evil may be said to have survived the decay of Chivalry, to have extended itself to the new world, and to have occasioned those horrors with which it was devastated for ages after its first discovery. The Spanish conquerors of South America were not, indeed, knights-errant, but the nature of their enterprises, as well as the mode in which they were conducted, partook deeply of the spirit of Chivalry. In no country of Europe had this spirit sunk so deeply and spread so wide as in Spain. The extravagant positions respecting the point of honour, and the romantic summons which Chivalry proclaimed to deeds of danger and glory, suited the ardent and somewhat oriental character of the Spaniards, a people more remarkable for force of imagination, and depth of feeling, than for wit or understanding. Chivalry, in Spain, was embittered by a double proportion of intolerant bigotry, owing to their constant and inveterate wars with the Moorish invaders. The strain of sentiment, therefore, which Chivalry inspired, continued for a long time to mark the manners of Spain after the decay of its positive institutions, as the beams of the sun tinge its horizon after the setting of his orb. The warriors whom she sent to the new world sought and found marvels which resembled those of romance; they achieved deeds of valour against such odds of numbers as are only recorded in the annals of knight-errantry; and alas! they followed their prototypes in that indifference for human life which is the usual companion of intolerant zeal. Avarice, indeed, brought her more sordid shades to complete the gloomy picture; and avarice was unknown to the institutions of Chivalry. The intolerant zeal, however, which overthrew the altars of the Indians by violence, instead of assailing their errors by reason, and which imputed to them as crimes their ignorance of a religion which had never been preached to them, and their rejection of speculative doctrines of faith propounded by persons whose practice was so ill calculated to recommend them—all these may be traced to the

Chivalry. spirit of Chivalry, and the military devotion of its professors.

The religion of the knights, like that of the times, was debased by superstition. Each champion had his favourite saint, to whom he addressed himself upon special occasions of danger, and to whom, after the influence of his lady's eyes, he was wont to ascribe the honour of his conquests. St Michael, the leader of banded Seraphim, and the personal antagonist of Satan,—St George, St James, and St Martin, all of whom popular faith had invested with the honours of Chivalry,—were frequently selected as the appropriate champions of the militant adventurers yet on earth. The knights used their names adjoined to their own as their insignia, watch-word, or signal for battle. Edward III. fighting valiantly in a night-skirmish before the gates of Calais, was heard to accompany each blow he struck with the invocation of his tutelar saints, Ha! Saint Edward! ha! St George! But the Virgin Mary, to whom their superstition ascribed the qualities of youth, beauty, and sweetness, which they prized in their terrestrial mistresses, was an especial object of the devotion of the followers of Chivalry, as of all other good Catholics. Tournaments were undertaken, and feats of arms performed in her honour, as in that of an earthly mistress, and the veneration with which she was regarded seems occasionally to have partaken of the character of romantic affection. She was often held to return this love by singular marks of her favour and protection. During an expedition of the Christians to the coast of Africa, Froissart informs us that a large black dog was frequently seen in their camp, which barked furiously whenever the infidels approached it by night, and rendered such service to the Christian adventurers by its vigilance, that with one consent they named it "The Dog of our Lady."

But although, as is incidental to human institutions, the mixture of devotion in the military character of the knight degenerated into brutal intolerance and superstition, in its practical effects, nothing could be more beautiful and praiseworthy than the theory on which it was grounded. That the soldier drawing the sword in defence of his country and its liberties, or of the oppressed innocence of damsels, widows, and orphans, or in support of religious rights, for which those to whom they belonged were disqualified by their profession to combat in person,—that he should blend with all the feelings which these offices inspired, a deep sense of devotion, exalting him above the advantage and even the fame which he himself might derive from victory, and giving dignity to defeat itself, as a lesson of divine chastisement and humiliation; that the knight on whose valour his countrymen were to rely in danger should set them an example in observing the duties and precepts of religion, are circumstances so well qualified to soften, to dignify, and to grace the profession of arms, that we cannot but regret their tendency to degenerate into a ferocious propensity to bigotry, persecution, and intolerance. Such, however, is the tendency of all human institutions, which, however fairly framed in theory, are in practice corrupted by our evil passions, until the results which

flow from them become the very reverse of what was to have been expected and desired. *Chivalry.*

The next ingredient in the spirit of Chivalry, second in force only to the religious zeal of its professors, and frequently predominating over it, was a devotion to the female sex, and particularly to her whom each knight selected as the chief object of his affection, of a nature so extravagant and unbounded as to approach to a sort of idolatry.

The original source of this sentiment is to be found, like that of Chivalry itself, in the customs and habits of the northern tribes, who possessed, even in their rudest state, so many honourable and manly distinctions, over all the other nations in the same stage of society. The chaste and temperate habits of these youth, and the opinion that it was dishonourable to hold sexual intercourse until the twentieth year was attained, was in the highest degree favourable not only to the morals and health of the ancient Germans, but must have contributed greatly to place the females in that dignified and respectable rank which they held in society. Nothing tends so much to blunt the feelings, to harden the heart, and to destroy the imagination, as the worship of the Vaga Venus in early youth. Wherever women have been considered as the early, willing, and accommodating slaves of the voluptuousness of the other sex, their character has become degraded, and they have sunk into domestic drudges and bondswomen among the poor,—the slaves of a harem among the more wealthy. On the other hand, the men, easily and early sated with indulgences, which soon lose their poignancy when the senses only are interested, become first indifferent, then harsh and brutal to the unfortunate slaves of their pleasures. The sated lover,—and perhaps it is the most brutal part of humanity,—is soon converted into the capricious tyrant, like the successful seducer of the modern poet.

"Hard! with their fears and terrors to behold
The cause of all, the faithless lover cold,
Impatient grown at every wish denied,
And barely civil, soothed and gratified."

Crabbe's *Borough*, p. 213.

Habitual indulgence seeks change of objects to relieve satiety. Hence polygamy, and all its brutalizing consequences, which were happily unknown to our Gothic ancestors. The virtuous and manly restraints imposed on their youth were highly calculated to exalt the character of both sexes, and especially to raise the females in their own eyes and those of their lovers. They were led to regard themselves, not as the passive slaves of pleasure, but as the objects of a prolonged and respectful affection, which could only be finally gratified when their lovers had attained the age of mature reason, and was capable to govern and to defend the family which should arise around them. With the young man imagination and sentiment combined to heighten his ideas of a pleasure which nature instructed him to seek, and which the wise laws of his country prevented him from prematurely aspiring to share. To a youth so situated, the maiden on whom he placed his affections became an object of awe as well as of affection; the passion which he indulged for her was of a nature as

Chivalry.

timid and pure as engrossing and powerful; the minds of the parties became united before the joining of their hands, and a moral union preceded the mere intercourse of the sexes.

The marriages formed under these happy auspices were, in general, happy and affectionate. Adultery was unfrequent, and punished with the utmost rigour; nor could she who had undergone the penalty of such a crime find a second husband, however distinguished by beauty, birth, or wealth. (Taciti *Germania*.) The awe and devotion with which the lover had regarded his destined bride during the years in which the German youth were enjoined celibacy, became regard and affection in the husband towards the sharer of his labours and the mistress of his household. The matron maintained that rank in society which love had assigned to the maiden. No one then, says the Roman historian, dared to ridicule the sacred union of marriage, or to term an infingement of its laws a compliance with the manners of the age. The German wife, once married, seldom endeavoured to form a second union, but continued, in honoured widowhood, to direct and manage the family of her deceased husband. This habitual subjection of sensuality to sentiment, these plain, simple, virtuous, and temperate manners of the German females, placed the females in that high rank of society which the sex occupies when its conduct is estimable, and from which it as certainly declines in ages or climates prone to luxurious indulgence. The superintendence of the domestic affairs was assigned to the German women, a duty in which themenseldom interfered, unless when rendered by age or wounds incapable of warfare. They were capable of exercising the supreme authority in their tribe, and of holding the honours of the priesthood. But the influence of the women in a German tribe, as well as their duties in war, will be best understood from the words of Tacitus. "It is the principal incitement to the courage of the Germans, that in battle their separate troops or columns are not arranged promiscuously as chance directs, but consist each of an united family or clan with its relatives. Their dearest pledges are placed in the vicinity, whence may be heard the cries of their females, the wailings of their infants, whom each accounts the most sacred witnesses and the dearest eulogists of his valour. The wounded repair to their mothers and spouses, who hesitate not to number their wounds, and to suck the blood that flows from them. The females carry refreshment to those engaged in the contest, and encourage them by their exhortations. It is related, that armies, when disordered and about to give way, have renewed the contest at the instance of the women; moved by the earnestness of their entreaties, their exposed bosoms, and the danger of approaching captivity;—a doom which they dread more on account of their females than even on their own;—inasmuch, that these German states are most effectually bound to obedience, among the number of whose hostages there are noble damsels as well as men. They deem, indeed, that there resides in the female sex something sacred and capable of presaging the future; nor do they scorn their advice or neglect their responses. In the time of Vespasian we have seen Velleda long

hold the rank of a deity in most of the German states; and, in former times, they venerated Aurinia and other females; not, however, from mere flattery, nor yet in the character of actual goddesses." The tales and *Sagas* of the north, in which females often act the most distinguished part, might also be quoted as proofs of the rank which they held in society. We find them separating the most desperate frays by their presence, their commands, or their mantles, which they threw over the levelled weapons of the combatants. Nor were their rights less extensive than their authority. In the *Eyrbyggja Saga* we are informed, that Thordisa, the mother of the celebrated Pontiff Snorro, and wife of Biarko of Stelgafels, received a blow from her husband. The provocation was strong, for the matron had, in her husband's house and at his table, attempted to stab his guest Eyalf Graie, on account of his having slain one of her relations. Yet so little did this provocation justify the offence, that, in the presence of the comitia, or public assembly of the tribe, Thordisa invoked witnesses to bear testimony that she divorced her husband on account of his having raised his hand against her person. And such were the rights of a northern *mater-familias*, that the divorce and a division of goods immediately took place between the husband and wife, although the violence of which Thordisa complained was occasioned by her own attempt to murder a guest.

We have traced the ideas of the Gothic tribes on this important point the more at length, because they show, that the character of veneration, sanctity, and inviolability attached to the female character, together with the important part assigned to them in society, were brought with them from their native forests, and had existence long before the chivalrous institutions in which they made so remarkable a feature. They easily became amalgamated in a system so well fitted to adopt whatever was romantic and enthusiastic in manners or sentiment. Amid the various duties of knighthood, that of protecting the female sex, respecting their persons, and redressing their wrongs, becoming the champion of their cause, and the chastiser of those by whom they were injured, was presented as one of the principal objects of the institution. Their oath bound the new-made knights to defend the cause of all women without exception; and the most pressing way of conjuring them to grant a boon was to implore it in the name of God and the ladies. The cause of a distressed lady was, in many instances, preferable to that even of the country to which the knight belonged. Thus, the Captal de Buche, though an English subject, did not hesitate to unite his troops with those of the Comte de Foix, to relieve the ladies in a town where they were besieged and threatened with violence by the insurgent peasantry. The looks, the words, the sign of a lady were accounted to make knights at time of need perform double their usual deeds of strength and valour. At tournaments and in combats, the voices of the ladies were heard like those of the German females in former battles, calling on the knights to remember their fame, and exert themselves to the uttermost. "Think gentle knights," was their cry, "upon the wool of your breasts, the nerve of your arms, the

Chivalry.

Chivalry. love you cherish in your hearts, and do valiantly, for ladies behold you." The corresponding shouts of the combatants were, "Love of ladies! Death of warriors! On, valiant knights, for you fight under fair eyes."

Where the honour or love of a lady was at stake, the fairest prize was held out to the victorious knight, and champions from every quarter were sure to hasten to combat in a cause so popular. Chaucer, when he describes the assembly of the knights who came with Arcite and Palemon to fight for the love of the fair Emilie, describes the manners of his age in the following lines.

"For every knight that loved chivalry,
And would his thanks have a peasant name,
Hath pray'd that he might ben of that game,
And well was him that thereto chosen was
For if there fell to-morrow such a case,
Ye knowen well that every lusty knight
That loveth par amour, and hath his night,
Were it in Engellonde, or elleswhere,
They wold hir thanks willen to be there.
To fight for a lady! Ah! Benedicite
It were a lusty sight for to see."

It is needless to multiply quotations on a subject so trite and well known. The defence of the female sex in general, the regard due to their honour, the subservience paid to their commands, the reverend awe and courtesy, which, in their presence, forbear all unseemly words and actions, were so blended with the institution of chivalry, as to form its very essence.

But it was not enough that the "very perfect, gentle knight," should reverence the fair sex in general. It was essential to his character that he should select, as his proper choice, "a lady and a love," to be the polar star of his thoughts, the mistress of his affections, and the directress of his actions. In her service, he was to observe the duties of loyalty, faith, secrecy, and reverence. Without such an empress of his heart, a knight, in the phrase of the times, was a ship without a rudder, a horse without a bridle, a sword without a hilt; a being, in short, devoid of that ruling guidance and intelligence, which ought to inspire his bravery, and direct his actions.

The Dame des Belles Cousines, having cast her eyes upon the little Jean de Saintré, then a page of honour at court, demanded of him the name of his mistress and his love, on whom his affections were fixed. The poor boy, thus pressed, replied, that the first object of his love was the lady his mother, and the next his sister Jacqueline. "Jouvencel," replied the inquisitive lady, who had her own reasons for not being contented with this simple answer, "we do not now talk of the affection due to your mother and sister; I desire to know the name of the lady whom you love *par amours*." "In faith, madam," said the poor page, to whom the mysteries of chivalry, as well as of love, were yet unknown, "I love no one *par amours*."—"Ah, false gentleman, and traitor to the laws of chivalry," returned the lady, "dare you say that you love no lady? well may we perceive your falsehood and crafty spirit by such an avowal. Whence were derived the great valour and the high

achievements of Lancelot of Gawain, of Tristrem, of Giron the Courteous, and of other heroes of the Round Table,—whence those of Panthus, and of so many other valiant knights and squires of this realm, whose names I could enumerate had I time,—whence the exaltation of many whom I myself have known to arise to high dignity and renown, except from their animating desire to maintain themselves in the grace and favour of their ladies, without which main-spring to exertion and valour, they must have remained unknown and insignificant. And do you, coward page, now dare to aver, that you have no lady, and desire to have none? Hence false heart that thou art." To avoid these bitter reproaches, the simple page named as his lady and love *par amour* Matheline de Coucy, a child of ten years old. The answer of the Dame des Belles Cousines, after she had indulged in the mirth which his answer prompted, instructed him how to place his affections more advantageously; and as the former part of the quotation may show the reader how essential it was to the profession of chivalry, that every one of its professors should elect a lady of his affections, that which follows explains the principles on which his choice should be regulated. "Matheline," said the lady, "is indeed a pretty girl, and of high rank, and better lineage than appertains to you. But what good, what profit, what honour, what advantage, what comfort, what aid, what council for advancing you in the ranks of chivalry, can you derive from such a choice? Sir, you ought to choose a lady of high and noble blood, who has the talent and means to counsel and aid you at your need, and her you ought to serve so truly, and love so loyally, that she must be compelled to acknowledge the true and honourable affection which you bear to her. For believe there is no lady, however cruel and haughty, but through length of faithful service will be brought to acknowledge and reward loyal affection with some portion of pity, compassion, or mercy. In this manner, you will attain the praise of a worthy knight, and till you follow such a course, I would not give an apple for you or your achievements." The lady then proceeds to lecture the acolyte of Chivalry at considerable length on the seven mortal sins, and the way in which the true amorous knight may eschew commission of them. Still, however, the saving grace inculcated in her sermon was fidelity and secrecy in the service of the mistress whom he should love *par amours*. She proves, by the aid of quotations from the Scripture, the fathers of the church, and the ancient philosophers, that the true and faithful lover can never fall into the crimes of Pride, Anger, Envy, Sloth, or Gluttony. From each of these his true faith is held to warrant and defend him. Nay, so pure was the nature of the flame which she recommended, that she maintained it to be inconsistent even with the seventh sin of Chambering and Wantonness, to which it might seem too nearly allied. The least dishonest thought or action was, according to her doctrine, sufficient to forfeit the chivalrous lover the favour of his lady. It seems, however, that the greater part of her charge concerning incontinence is levelled against such as haunted the receptacles of open vice; and that she reserved an exception (of

Chivalry. which, in the course of the history, she made liberal use) in favour of the intercourse which, in all love, honour, and secrecy, might take place when the favoured and faithful knight had obtained, by long service, the boon of amorous mercy from the lady whom he loved *par amours*. The last encouragement which the Dames des Belles Cousines held out to Saintré, in order to excite his ambition, and induce him to fix his passion upon a lady of elevated birth, rank, and sentiment, is also worthy of being quoted, since it shows that it was the prerogative of Chivalry to abrogate the distinctions of rank, and elevate the hopes of the knight, whose sole patrimony was his arms and valour, to the high-born and princely dame, before whom he carved as a sewer.

"How is it possible for me," replied poor Saintré, after having heard out the unmercifully long lecture of the Dame des Belles Cousines, "to find a lady, such as you describe, who will accept of my service, and requite the affection of such a one as I am?"—"And why should you not find her?" answered the lady preceptress. "Are you not gently born? Are you not a fair and proper youth? Have you not eyes to look on her—ears to hear her—a tongue to plead your cause to her—hands to serve her—feet to move at her bidding—body and heart to accomplish loyally her commands? And, having all these, can you doubt to adventure yourself in the service of any lady whatsoever?"

In these extracts is painted the actual manners of the age of chivalry. The necessity of the perfect knight having a mistress, whom he loved *par amours*, the duty of dedicating his time to obey her commands, however capricious, and his strength to execute extravagant feats of valour, which might redound to her praise,—for all that was done for her sake, and under her auspices, was counted her merit, as the victories of their generals were ascribed to the Roman Emperors,—was not a whit less necessary to complete the character of a good knight than the Dame des Belles Cousines represented it.

It was the especial pride of each distinguished champion, to maintain, against all others, the superior worth, beauty, and accomplishments of his lady; to bear her picture from court to court, and support, with lance and sword, her superiority to all other dames, abroad or at home. To break a spear for the love of their ladies, was a challenge courteously given, and gently accepted, among all true followers of chivalry; and history and romance are alike filled with the tilts and tournaments which took place upon this argument, which was ever ready and ever acceptable. Indeed, whatever the subject of the tournament had been, the lists were never closed until a solemn course had been made in honour of the ladies.

There were knights yet more adventurous, who sought to distinguish themselves by singular and uncommon feats of arms in honour of their mistresses, and such was usually the cause of the whimsical and extravagant vows of arms which we have subsequently to notice. To combat against extravagant odds, to fight amid the press of armed knights

without some essential part of their armour, to do some deed of audacious valour in face of friend and foe, were the services by which the knights strove to recommend themselves, or which their mistresses (very justly so called) imposed on them as proofs of their affection.

On such occasions, the favoured knight, as he wore the colours and badge of the lady of his affections, usually exerted his ingenuity in inventing some device or cognisance which might express their affection, either openly, as boasting of it in the eye of the world, or in such mysterious mode of indication as should only be understood by the beloved person, if circumstances did not permit an avowal of his passion. Among the earliest instances of the use of the English language at the court of the Norman monarchs, is the distich painted in the shield of Edward III. under the figure of a white swan, being the device which that warlike monarch wore at a tourney, at Windsor.

"Ha! ha! the white swan,
By God his soul, I am thy man."

The choice of these devices was a very serious matter; and the usurpation of such as any knight had previously used and adopted, was often the foundation of a regular quarrel, of which many instances occur in Froissart and other writers.

The ladies, bound as they were in honour to requite the passion of their knights, were wont, on such occasions, to dignify them by the present of a scarf, ribbon, or glove, which was to be worn in the press of battle and tournament. These marks of favour they displayed on their helmets, and they were accounted the best incentives to deeds of valour. The custom appears to have prevailed in France to a late period, though polluted with the grossness so often mixed with the affected refinement and gallantry of that nation. In the attack made by the Duke of Buckingham upon the Isle of Rhé, favours were found on the persons of many of the French soldiers who fell at the skirmish on the landing, but for the manner in which they were disposed, we are compelled to refer to Howel and Wilson.

Sometimes the ladies, in conferring these tokens of their favour, clogged them with the most extravagant and severe conditions. But the lover had this advantage in such cases, that if he ventured to encounter the hazard imposed, and chanced to survive it, he had, according to the fashion of the age, the right of exacting, from the lady, favours corresponding in importance. The annals of Chivalry abound with stories of cruel and cold fair ones who subjected their lovers to extremes of danger, in hopes that they might get rid of their addresses, but were, upon their unexpected success, caught in their own snare, and, as ladies who would not have their name made the theme of reproach by every minstrel, compelled to recompense the deeds which their champion had achieved in their name. There are instances in which the lover used his right of reprisals with some rigour, as in the well known *fabliau* of the three knights and the shift; in which

Chivalry. a lady proposes to her three lovers, successively, the task of entering, unarmed, into the *melée* of a tournament arrayed only in one of her shifts. The perilous proposal is declined by two of the knights and accepted by the third, who thrusts himself, in the unprotected state required, into all the hazards of the tournament, sustains many wounds, and carries off the prize of the day. On the next day the husband of the lady (for she was married) was to give a superb banquet to the knights and nobles who had attended the tourney. The wounded victor sends the shift back to its owner, with his request, that she would wear it over her rich dress on this solemn occasion, soiled and torn as it was, and stained all over with the blood of its late wearer. The lady did not hesitate to comply, declaring, that she regarded this shift, stained with the blood of her "fair friend as more precious than if it were of the most costly materials." Jaques de Basin, the minstrel, who relates this curious tale, is at a loss to say whether the palm of true love should be given to the knight or to the lady on this remarkable occasion. The husband, he assures us, had the good sense to seem to perceive nothing uncommon in the singular vestment with which his lady was attired, and the rest of the good company highly admired her courageous requital of the knight's gallantry.

Sometimes the patience of the lover was worn out by the cold-hearted vanity which thrust him on such perilous enterprises. At the court of one of the German Emperors, while some ladies and gallants of the court were looking into a den where two lions were confined, one of them purposely let her glove fall within the palisade which inclosed the animals, and commanded her lover, as a true knight, to fetch it out to her. He did not hesitate to obey; jumped over the inclosure; threw his mantle towards the animals as they sprung at him; snatched up the glove, and regained the outside of the palisade. But when in safety, he proclaimed aloud, that what he had achieved was done for the sake of his own reputation, and not for that of a false lady, who could for her sport and cold-blooded vanity face a brave man on a duel so desperate. And with the applause of all that were present, he renounced her love for ever.

This, however, was an uncommon circumstance. In general, the lady was supposed to have her lover's character as much at heart as her own, and to mean, by pushing him upon enterprises of hazard, only to give him an opportunity of meriting her good graces, which she could not with honour confer upon one undistinguished by deeds of chivalry. An affecting instance is given by Godscroft.

At the time when the Scotch were struggling to recover from the usurpation of Edward I., the castle of Douglas was repeatedly garrisoned by the English, and these garrisons were as frequently surprised, and cut to pieces by the good Lord James of Douglas, who, lying in the mountainous wilds of Cairn-table, and favoured by the intelligence which he maintained among his vassals, took opportunity of the slightest relaxation of vigilance to surprise the fortress. At length, a fair dame of England announced to the numerous suitors who sought her

Chivalry. hand, that she would confer it on the man who should keep the perilous castle of Douglas (so it was called) for a year and a day. The knight who undertook this dangerous task at her request discharged his duty like a careful soldier for several months, and the lady relenting at the prospect of his continued absence, sent a letter to recall him, declaring she held his probation as accomplished. In the meantime, however, he had received a defiance from Douglas, threatening him, that, let him use his utmost vigilance, he would recover from him his father's castle before Palm-Sunday. The English knight deemed that he could not in honour leave the castle till this day was past; and on the very eve of Palm-Sunday was surprised and slain with the lady's letter in his pocket, the perusal whereof greatly grieved the good Lord James of Douglas.

We are left much to our own conjectures on the appearance and manners of these haughty beauties, who were wooed with sword and lance, whose favours were bought at the expence of such dear and desperate perils, and who were worshipped, like heathen deities, with human sacrifices. The character of the ladies of the ages of chivalry was probably determined by that of the men, to whom it sometimes approached. Most of these heroines were educated to understand the treatment of wounds, not only of the heart, but of the sword; and in romance, at least, the quality of leech-craft (practised by the Lady Bountifuls of the last generation) was essential to the character of an accomplished princess. They sometimes trespassed on the province of their lovers, and actually took up arms. The Countess de Montfort in Bretagne is celebrated by Froissart for the gallantry with which she defended her castle, when besieged by the English; and the old Prior of Lochleven in Scotland is equally diffuse in the praise of Black Agnes, Countess of March, who, in the reign of Edward III. held out the castle of Dunbar against the English. She appeared on the battlements with a white handkerchief in her hands, and wiped the walls in derision where they had been struck by stones from the English engines. When Montagu, Earl of Salisbury, brought up to the walls a military engine, like the Roman *testudo*, called a sow, she exclaimed in rhyme,

Beware Montagu,
For farrow shall thy sow.

A huge rock discharged from the battlements dashed the sow to pieces, and the English soldiers who escaped from its ruins were called by the Countess in derision Montague's pigs.

The nature of the conferences between these high-minded heroines and their lovers, was somewhat peculiar. Their delectations were in tales of warlike exploits, and in discourse of hunting and hawking. But when these topics were exhausted, they found in metaphysical discussions of nice questions concerning the passion of love, an endless source of interesting disquisition. The idea and definition of a true and pure passion, illustrated by an hundred imaginary cases devised on purpose, were managed in the same manner in which the schoolmen of

Chivalry. the day agitated their points of metaphysical theology. The Scotists and the Thomists, whose useless and nonsensical debates cumbered the world with so many volumes of absurd disquisition upon the most extravagant points of polemical divinity, saw their theological labours rivalled in the courts of love, where the most abstracted reasoning was employed in discussing subtle questions upon the exaggerated hopes, fears, doubts, and suspicions of lovers, the circumstances of whose supposed cases were often ridiculous, sometimes criminal, sometimes licentious, and almost always puerile and extravagant. These particulars will fall to be more fully illustrated under the article *TROUBADOUR*. In the meanwhile, it is sufficient to state, that the discussions in the Courts of Love regarded such important and interesting questions, as, Whether his love be most meritorious who has formed his passion entirely on hearing, or his who has actually seen his mistress? with others of a tendency equally edifying.

Extremes of every kind border on each other; and as the devotion of the knights of chivalry degenerated into superstition, the Platonic refinements and subtleties of amorous passion which they professed, were sometimes compatible with very coarse and gross debauchery. We have seen that they derived from the Gothic tribes that high and reverential devotion to the female sex, which forms the strongest tint in the manners of chivalry. But with the simplicity of these ancient times they lost their innocence; and woman, though still worshipped with enthusiasm as in the German forests, did not continue to be (in all cases at least) the same pure object of worship. The marriage-tie ceased to be respected; and as the youthful knights had seldom the means or inclination to encumber themselves with wives and families, their lady-love was often chosen among the married ladies of the court. It is true, that such a connection was supposed to be consistent with all respect and honour, and was regarded by the world, and sometimes by the husband, as a high strain of Platonic sentiment, through which the character of its object in no respect suffered. But nature vindicated herself for the violence offered to her; and while the metaphysical students and pleaders in the Courts of Love professed to aspire but to the lip or hand of their ladies, and to make a merit of renouncing all farther intrusion on their bounties, they privately indulged themselves in loves which had very little either of delicacy or sentiment. In the romance of the *Petit Jehan de Saintré*, that self-same Lady des Belles Cousines, who lectures so learnedly upon the seven mortal sins, not only confesses on her deserving lover "le don d'amoureux merci," but enters into a very unworthy and disgraceful intrigue with a stout broad-shouldered abbot, into which no sentiment whatever can be supposed to enter. The romance of *Tirante the White*, praised by Cervantes as a faithful picture of the knights and ladies of his age, seems to have been written in an actual brothel, and, contrasted with others, may lead us to suspect that their purity is that of romance, its profligacy that of reality. This licence was greatly increased by the *Crusades*, from which the survivors of these wild expeditions brought back the corrupt-

ed morals of the east, to avenge the injuries they had inflicted on its inhabitants. Joinville has informed us of the complaints which Saint Louis made to him in confidence of the debaucheries practised in his own royal tent, by his attendants, in this holy expedition. And the ignominious punishment to which he subjected a knight, detected in such excesses, shows what severe remedies he judged necessary to stem the increase of libertinism.

Indeed, the gross licence which was practised during the middle ages, may be well estimated by the vulgar and obscene language that was currently used in tales and fictions addressed to the young and noble of both sexes. In the romance of the *Round Table*, as Ascham sternly states, little was to be learned but examples of homicide and adultery, although he had himself seen it admitted to the anti-chamber of princes, when it was held a crime but to be possessed of the Word of God. In the romance of *Amadis de Gaul*, and many others, the heroines, without censure or imputation, confer on their lovers the rights of a husband before the ceremony of the church gave them a title to the name. These are serious narrations, in which decorum, at least, is rarely violated. But the comic tales are of a grosser cast.

The *Canterbury Tales* of Chaucer contain many narratives of which, not only the diction, but the whole turn of the narrative, is extremely gross. Yet it does not seem to have occurred to the author, a man of rank and fashion, that they were improper to be recited, either in the presence of the prioress and her votaries, or in that of the noble knight who

of his port was meek as is a maid,
And never yet no villany he said.

And he makes but a light apology for including the disasters of the *Millar of Trompington*, or of *Absalom the Gentle Clerk* in the same series of narrations with the *Knight's Tale*. Many of Bandello's most profligate novels are expressly dedicated to females of rank and consideration. And, to conclude, the *Fabliaux*, published by Barbazan and Le Grand, are frequently as revolting, from their naked grossness, as interesting from the lively pictures which they present of life and manners. Yet these were the chosen literary pastimes of the fair and the gay, during the times of Chivalry, listened to, we cannot but suppose, with an interest considerably superior to that exhibited by the yawning audience who heard the theses of the Courts of Love attacked and supported in logical form, and with metaphysical subtlety.

Should the manners of the times appear inconsistent in these respects which we have noticed, we must remember that we are ourselves variable and inconsistent animals, and that, perhaps, the surest mode of introducing and encouraging any particular vice, is to rank the corresponding virtue at a pitch unnatural in itself, and beyond the ordinary attainment of humanity. The vows of celibacy introduced profligacy among the Catholic clergy, as the high-flown and overtrained Platonism of the professors of Chivalry favoured the increase of licence and debauchery.

After the love of God and of his lady, the Preux

Chivalry. Chevalier was to be guided by that of glory and renown. He was bound by his vow to seek out adventures of risk and peril, and never to abstain from the quest which he might undertake, for any unexpected odds of opposition which he might encounter. It was not indeed the sober and regulated exercise of valour, but its fanaticism, which the genius of chivalry demanded of its followers. Enterprizes the most extravagant in conception, the most difficult in execution, the most useless when achieved, were those by which an adventurous knight chose to distinguish himself. There were solemn occasions also, on which these displays of chivalrous enthusiasm were specially expected and called for. It is only sufficient to name the tournaments, single combats, and solemn banquets, at which vows of chivalry were usually formed and proclaimed.

The tournaments were uniformly performed and frequented by the choicest and noblest youth in Europe, until the fatal accident of Henry II. after which they fell gradually into disuse. It was in vain that, from the various accidents to which they gave rise, these dangerous amusements were prohibited by the heads of the Christian church. The Popes, infallible as they were deemed, might direct, but could not curb the military spirit of chivalry; they could excite crusades, but they could not abolish tournaments. Their laws, customs, and regulations, will fall properly under a separate article. It is here sufficient to observe, that these military games were of two kinds. In the most ancient, meaning, "nothing in hate but all in honour," the adventurous knights fought with sharp swords and lances as in the day of battle. Even then, however, the number of blows was usually regulated, or, in case of a general combat, some rules were laid down to prevent too much slaughter. The regulations of Duke Theseus for the tournament at Athens, as narrated by Chaucer in the *Knights Tale*, may give a good example of these restrictions. When the combatants fought on foot, it was prohibited to strike otherwise than at the head or body; the number of strokes to be dealt with the sword and battle-axe were carefully numbered and limited, as well as the careers to be run with the lance. In these circumstances alone, the combats at *outrance* as they were called, differed from encounters in actual war.

In process of time, the dangers of the solemn justs, held under the authority of princes, were modified by the introduction of arms of courtesy as they were termed, lances, namely, without heads, and with round braces of wood at the extremity called *rockets*, and swords without points, and with blunted edges. But the risk continued great from bruises, falls, and the closeness of the defensive armour of the times, in which the wearers were often smothered. The weapons at *outrance* were afterwards chiefly used when knights of different and hostile countries engaged by appointment, or when some adventurous gallants took upon them the execution of an enterprise of arms (*pas d'armes*) in which they, as challengers, undertook, for a certain time, and under certain conditions, to support the honour of their country or their mistress against all comers. These enterprises often ended fatally, but the knights who undertook them were received in the

foreign countries which they visited in accomplishment of their challenge, with the highest deference and honour; their arrival was considered as affording a subject of sport and jubilee to all ranks; and when any mischance befel them, such as that of De Lindsay, who, in a tournament at Berwick, had his helmet nailed to his skull, by the truncheon of a lance which penetrated both, and died after devoutly confessing himself in the casque from which they could not disengage him, the knights who looked on prayed that God would vouchsafe them in his mercy a death so fair and so honourable. Stories of such challenges, with the minute details of the events of the combat, form frequent features in the histories of the age.

The contests of the tournament and the *pas d'armes* were undertaken merely in sport, and for thirst of honour. But the laws of the period afforded the adventurous knight other and more serious combats, in which he might exercise his valour. The custom of trying all doubtful cases by the body of a man, or, as it was otherwise expressed, by the judgment of God—in plain words, by referring the decision to the issue of a duel, prevailed universally among the Gothic tribes, from the highest antiquity. A *salvo* was devised, for the obvious absurdity of calling upon the weak to encounter the strong, a churchman to oppose a soldier, or age to meet in the lists with activity and youth. It was held that either party might appear personally, or by his champion. This sage regulation gave exercise for the valour of the knights, who were bound by their oaths to maintain the cause of those who had no other protector. And, indeed, there is good reason to think, that the inconveniences and injustice of a law so absurd in itself as that of judicial combat, were evaded and mitigated by the institutions of Chivalry, since, among the number of knights who were eagerly hunting after opportunities of military distinction, a party incapable of supporting his own cause by combat could have little difficulty in finding a formidable substitute; so that no one, however bold and confident, could prosecute an unjust cause to the uttermost, without the risk of encountering some champion of the innocent party from among the number of hardy knights who traversed every country seeking ostensible cause of battle.

Besides these formal combats, it was usual for the adventurous knight to display his courage by stationing himself at some pass in a forest, on a bridge, or elsewhere, compelling all passers to avouch the superiority of his own valour, and the beauty of his mistress, or otherwise to engage with him in single combat. When Alexius Comnenus received the homage of the crusaders, seated upon his throne, previous to their crossing the Hellespont, during the first crusade, a French baron seated himself by the side of the Emperor of the East. He was reproved by Baldwin, and answered in his native language, "What ill-taught clown is this, who dares to keep his seat when the flower of the European nobility are standing around him!" The Emperor, dissembling his indignation, desired to know the birth and condition of the audacious Frank. "I am," replied the baron, "of the noblest race of France. For the rest, I only know that there is near my

Chivalry.

Chivalry.

castle a spot where four roads meet, and near it a church where men, desirous of single combat, spend their time in prayer till some one shall accept their challenge. Often have I frequented that chapel, but never met I one who durst accept my defiance." Thus the Bridge of Rodomont, in the Orlando Furioso, and the valiant defiance which the knight of La Mancha hurled against the merchants of Toledo, who were bound to the fairs of Murcia, were neither fictions of Ariosto nor Cervantes, but had their prototypes in real story. The chivalrous custom of defying all and sundry to mortal combat, subsisted in the borders until the days of Queen Elizabeth, when the worthy Bernard Gilpin found in his church of Houghton-le Spring a glove hung over the altar, which he was informed indicated a challenge to all who should take it down. The remnants of the judicial combats, and the enterprizes of arms, may be found in the duels of the present day. In former days they still more resembled each other: for, in the seventeenth century, not only the seconds on each side regularly engaged, but it was usual to have more seconds, even to the number of five or six; a custom pleasantly ridiculed by Lord Chesterfield, in one of the papers of *The World*. It is obvious that an usage, at once so ridiculous and so detrimental to the peace and happiness of society must give way, in proportion to the progress of common sense. The custom is in general upon the wane, even as far as respects single combat between men who have actually given or taken offence at each other. The general rules of good-breeding prevent causes of such disagreement from arising in the intercourse of society, and the forward duellist, who is solicitous in seeking them out, is generally accounted a vulgar and ferocious, as well as a dangerous character. At the same time, the habits derived from the days of chivalry still retain a striking effect on our manners, and have fully established a graceful as well as useful punctilio, which tends on the whole to the improvement of society. Every man is under the impression, that neither his strength, his wealth, his station, or his wit, will excuse him from answering, at the risk of his life, any unbecoming encroachment on the civility due to the weakest, the poorest, the least important, or the most modest member of the society in which he mingles. All too in the rank and station of gentlemen are forcibly called upon to remember, that they must resent the imputation of a voluntary falsehood as the most gross injury; that the rights of the weaker sex demand protection from every one who would hold a good character in society. In short, from the wild and overstrained courtesies of chivalry has been derived our present system of manners. It is not certainly faultless, and it is guarded by penalties which we must often regret as disproportionately severe. Yet it has a grace and dignity unknown to classic times, when women were slaves and men coarse and vulgar, or overbearing and brutal, as suited their own humour, without respect to that of the rest of their society.

II. Such being the tone and spirit of chivalry, derived

from love, devotion, and valour,—we have next to notice the special forms and laws of the order, which will be found to correspond in every respect to the spirit which they were designed to foster.

Chivalry.

The education of the future knight began at an early period. The care of the mother, after the first years of early youth were past, was deemed too tender, and the indulgences of the paternal roof too effeminate, for the future aspirant to the honours of chivalry. "Do you not bless God," said the Lady Mabel to her husband, the noble Duke Guerin of Montglaise, as on a solemn feast they looked on their four hopeful sons, "do you not bless God that has given you such a promising issue."—"Dame," replied Guerin, in the true spirit of the age, "so help me God and Saint Martin! nothing can do me greater despite than to look on these four great lurdanes, who, arrived at such an age, yet do nothing but eat the fat, and drink the sweet, and spend their time in idle amusement."* To counteract these habits of indulgence, the first step to the order of knighthood was the degree of PAGE.

Rules and Forms of Chivalry.

The young and noble stripling, generally about his twelfth year, was transferred from his father's house to that of some baron or noble knight, sedulously chosen by the anxious parent as that which had the best reputation for good order and discipline. The children of the first nobles and high crown-vassals were educated by the royal court. And, however the reins of discipline might be in particular cases relaxed, or become corrupted in latter days, the theory was uniformly excellent. The youth who was to learn modesty, obedience, and address in arms and horsemanship, was daily exercised in the use of arms, beginning with such as were suited to his strength. He was instructed how to manage a horse with grace and dexterity; how to use the bow and the sword; how to manage the lance, an art which was taught by making him ride a career against a wooden figure holding a buckler called a quintaine. This quintaine turned on an axis; and as there was a wooden sword in the other hand of the supposed opponent, the young cavalier, if he did not manage his horse and weapon with address, was liable to receive a blow when the shock of his charge made the quintaine spin round.

Besides these exercises, the noble youth was required to do the work which, in some respects, belonged to a menial, but not as a menial. He attended his lord during the chase, the rules of which, as an image of war, and as held the principal occupation of a gentleman during peace, were carefully inculcated. He was taught the principal blasts or notes of *venerie*, to be sounded when the hounds were uncoupled, when the prey was on foot, when he was brought to bay, and when he fell. This art did not tend solely to amusement. The "gentle damosel," to use the language of the times, learned to bear the fatigue, the hunger, and thirst, which huntsmen are exposed to. By the necessity of encountering and dispatching a stag, a boar, or a wolf, at bay, he learned promptitude and courage in the use of his weapons. The accuracy with which he was required to

Chivalry. study the tracks of the hunted animal's course gave him habits of attention and reflection. In the days and nights spent in the chase, amid wide and pathless forests, he acquired the art, so necessary to a soldier, of remarking and studying the face of the country. When benighted, he was taught to steer his course by the stars, if they were visible; if not, to make his couch with patience on the withered leaves, or in a tree. Had he lost his way by day-time, he distinguished the points of the compass by remarking which side of the trees were most covered with moss, and from which they threw their branches most freely, circumstances which, compared with the known course of the prevailing wind, afforded him the necessary information.

The ceremonial of the chase was to be acquired as well as its arts. To bridle or break the deer, (in French, *faire la curée*), in plain terms, to flay and disembowel the stag, a matter in which much precision was required, and the rules of which were ascribed to the celebrated Sir Tristram of Lioness, was an indispensable requisite of the page's education. Nor did his concern with the venison end here; he placed it on the table, waited during the banquet, and carved the ponderous dishes, when required or permitted to do so. Much grace and delicacy, it was supposed, might be displayed on these occasions; and, in one romance, we read of the high birth and breeding of a page being ascertained, by his scrupulously declining to use a towel to wipe his hands, when washed before he began to carve, and contenting himself with waving them in the air till they dried of themselves. It is, perhaps, difficult to estimate the force of this delicacy, unless by supposing that he had not a towel or napkin appropriated to his own separate use.

Amidst these various instructions, the page was often required to wait upon the ladies, rather as attending a sort of superior beings, to whom adoration and obsequious service were due, than as ministering to the convenience of human creatures like himself. The most modest demeanour, the most profound respect, was to be observed in the presence of these fair idols. Thus the veneration due to the female character was taught to the acolyte of chivalry, by his being placed so near female beauty, yet prohibited the familiarity which might discover female weakness. Love frequently mingled with this early devotion, and the connection betwixt some lady of distinction and her gallant knight, is often, in romantic fiction, supposed to have originated from such early affection. In a romance called *The Golden Thread*, (of which we have only seen a modern edition in German, but which has many features of originality), when the daughter of the Count bestows her annual gifts on her father's household, she gives the page Lcofrid, in derision, a single thread of gold tissue. To show the value which he places upon the most minute memorial, coming from such an hand, the youth opens a wound in his bosom, and deposits the precious thread in the neighbourhood of his heart. The Dame des belles Cousines, whom we have already mentioned, was assuredly not the only lady of high rank who was tempted to give a handsome young page the benefit of her experience in com-

pleting his education. This led the way to abuse; and the custom of breeding up youths as pages in the houses of the great, although it survived the decay of chivalry, was often rather the introduction to indolence, mischief, and debauchery, than to useful knowledge and the practice of arms. The proper purpose of this preliminary part of chivalrous education, are well given by one of the characters in Ben Jonson's *New Inn*, and he is answered by another, who alleges, with satire resembling that of Juvenal, the modern corruptions of the order of pages. Lord Lovel has requested mine Host to give him his son for a page. The Host answers, by declaring, he would rather hang his child with his own hand

"Than damn him to that desperate course of life.

Lovel. Call you that desperate which, by a line
Of institution from our ancestors,
Hath been derived down to us, and received
In a succession, for the noblest way
Of breeding up our youth in letters, arms,
Fair mien, discourses, civil exercises,
And all the blazon of a gentleman.
Where can he learn to vault, to ride, to fence.
To mar his body gracefully, to speak
His language purer, or to turn his mind
Or manners more to the harmony of nature
Than in those nurseries of nobility?

Host. Aye, that was when the nursery's self was noble,
And only virtue made it not the market."

And he replies, by enumerating instances of the decay of honour among the nobles, and of the debauchery of their household pages. In La Noue's *Political and Military Discourses* is a similar complaint of the hazards to which the morals of young gentlemen were exposed while acting in this domestic capacity. Nevertheless, the custom of having young gentlemen thus bred, continued, in a certain degree, down to the last century, although those destined to such employments became, by degrees, of a lower quality. In some few instances, the institution was maintained in its purity, and the page, when leaving the family in which he was educated, usually obtained a commission. The last instance we know, was that of a gentleman bred a page in the family of the Duchess of Buccleuch and Monmouth, who died during the present reign, a general-officer in his Majesty's service.

When advancing age and experience in the use **The Squire.**
of arms had qualified the page for the hardships and dangers of actual war, he was removed from the lowest to the second gradation of chivalry, and became an *Escuyer*, Esquire, or SQUIRE. The derivation of this phrase has been much contested. It has been generally supposed to be derived from its becoming the official duty of the esquire to carry the shield (*Escu*) of the knight his master, until he was about to engage the enemy. Others have fetched the epithet (more remotely certainly) from *Scuria* a stable, the charger of the knight being under the especial care of the squire. Others, again, ascribe the derivation of the word to the right which the squire himself had to carry a shield, and to blazon it with armorial bearings. This, in later times, became almost the exclusive meaning attached to the appellative esquire; and, accordingly, if the phrase now means anything, it means a gentleman having right to carry arms. There is reason, how-

Chivalry. ever, to think, that this is a secondary meaning of the word, for we do not find the word *Escuyer*, applied as a title of rank, until so late as the Ordinance of Blois, in 1579.

The candidate for the honours of chivalry, now an immediate attendant on the knight or nobleman, was withdrawn from the private apartments of the ladies, and only saw them upon occasions of stated ceremony. In great establishments, there were squires of different ranks, and destined for different services; but we shall confine ourselves to those general duties which properly belonged to the office. The squire assisted his master in the offices at once of a modern valet de chambre and groom—he attended to dress and to undress him, trained his horses to the menage, and kept his arms bright and burnished. He did the honours of the household to the strangers who visited it, and the reputation of the prince or great lord whom he served, was much exalted by the manner in which these courteous offices were discharged. In the words of Chaucer, describing the character of the squire,

“*Courteys he was, lowly and servisable,
And carf before his fader at the table.*”

The squire was also expected to perfect himself in the accomplishments of the period, and not only to be a master of the ceremonial of the feast, but to be capable of enlivening it by his powers of conversation. He was expected to understand chess, draughts, and other domestic games. Poetry and music, if he had any turn for these beautiful arts, and whatever other accomplishments could improve the mind or the person, were accounted to grace his station. And, accordingly, Chaucer's squire, besides that he was “singing or fluting all the day,”

“—Could songs make, and well indite,
Just, and eke dance, and well pourtray and write.”

Unquestionably, few possessed all these attributes; but the poet, with his usual precision and vivacity, has given us the picture of a perfect esquire.

To understand the squires' mode of life more particularly, it is necessary to consider that which was led in the courts and castles of the middle ages. Froissart has given us a very striking account of the mode of house-keeping in the family of Gaston, Earl of Foix, a prince whose court was considered as a first-rate nursery for the noble youth; and, from his lively description, we may, in some measure, conceive the mode in which the squires spent their time. Froissart abode in his house above twelve weeks, much recommended to the favourable notice of the earl, by his having brought with him a book containing all the songs, ballads, and virilays, which Wencislaws of Bohemia, the gentle Duke of Brabant, had made, and the historian himself had compiled or transcribed. “Every night, after supper,” says Froissart, “I read thereon to him, and while I read there was none durst speak any thing to interrupt me, so much did the earl delight in listening.” The quotation necessary to describe the Earl of Foix, and the economy of his household, must necessarily be a long one, but it is a picture, by the hand of an

inimitable artist, of a school of chivalry when chivalry was at its highest pitch, and we are unwilling to destroy the likeness by abridging it.

“This erle Gascone of Foix, with whom I was, at that tyme, he was of a fyftie yere of age and nyne: and, I say, I have in my tyme sene many knights, kynges, princes, and others, but I neuer saw none like him of personage, nor of so fayre forme, nor so well made; his vysage fayre, sanguyne, and smylyng, his eyen gray and amorous, wher as he lyst to set his regarde: in euery thyng he was so parfite that he can not be praised to moche; he loued that ought to be beloued, and hated that ought to be hated: he was a wyse knyght, of highe enterprise, and of good counsaile; he neuer had mysercant with hym; he sayd many orisons every day, a nocturn of the psalter, matyns of our Lady, of the Holy Goost, and of the crosse, and dirigè euery day; he gaue fyue florins, in small monies, at his gate to poore folkes for the loue of God; he was large and courtesse in gyftes; he could ryght well take wher it parteyned to hym, and to delyuer agayne wher as he ought; he loued houdes of all beestes, wynter and somer he loued huntyng; he neuer loued folly, outrage, nor foly larges; euery moneth he wolde knowe what he spendid; he tooke in his countre to receyue his reuenwes, and to serue him, notable persons, that is to saye, xii. recyours, and euer fro 11. monethes to two monethes, two of them shulde serue for his receyte; for, at the two monethes ende, he wolde change and put other two into that offyce; and one that he trusted best shulde be his comptroller, and to hym all other shulde accompt, and the comptroller shulde accōpt to hym by rolles and bokes written, and the comptes to remayne still with therle: he had certeyne cofers in his chambre, out of the whiche oftetymes he wolde take money to gyve to lordes, knightes, and squyers, suche as came to hym, for none shulde departe from him without some gift, and yet dayly he multiplyed his treasure, to resyst the aduētūres and fortunes that he doutid; he was of good and easy acquaintance with every man, and amorously wolde speke to thē; he was short in counsaile, and answers; he had four secretaries, and at his rising, they must ever be redy at his hande, without any callynge; and whan any letter were delyuered him, and that he had reced it, than he wolde calle them to write agayne, or els for some other thyng. In this estate therle of Foix lyued. And at mydnight, whan he came out of his chambre into the hall to supper, he had ever before hym xii. torches brennyng, borne by xii. varlettes standyng before his table all supper; they gaue a gret light, and the hall ever full of knightes and squyers, and many other tables dressed to suppe who wolde; ther was none should speke to hym at his table, but if he were called; his meate was lightlye wyldre foule, the legges and wynges alonely, and in the day he dyd but lytell eate and drike; he had great pleasure in armony of instrumētes; he coude do it right well hymselfe, he wolde have songes song before him, he wolde gladly se conseytes and fantasies at his table. And or I came to his court, I had ben in many courtes of kynges, dukes, princes, erles, and great ladyes, but I was neuer in none so go well liked me, nor ther was

Chivalry. none more reioysed in dedes of armes, than the erle dyde: ther was sene in his hall, chābre and court, knyghtes and squyers of honour goyng up and downe, and talking of armes and amours; all honour ther was found, all maner of tidynges of every realme and countre ther might be horde, for out of every cōutre there was resort, for the valyantesse of this erle." *

While the courage of the young aspirant to the honours of knighthood was animated, and his emulation excited by the society in which he was placed, and the conversation to which he listened,—while everything was done which the times admitted to refine his manners, and, in a certain degree, to cultivate his understanding; the personal exercises to which he had been trained, while a page, were now to be pursued with increasing assiduity, proportional to the increase of his strength. "He was taught," says a historian, speaking of Boucicaut, while a squire "to spring upon a horse, while armed at all points; to exercise himself in running, to strike for a length of time with the axe or club; to dance and throw somersets, entirely armed, excepting the helmet; to mount on horseback behind one of his comrades, by barely laying his hands on his sleeve; to raise himself betwixt two partition walls to any height, by placing his back against the one, and his knees and hands against the other; to mount a ladder, placed against a tower, upon the reverse or under side, solely by the aid of his hands, and without touching the rounds with his feet; to throw the javelin, to pitch the bar," to do all, in short, which could exercise the body to feats of strength and agility, in order to qualify him for the exploits of war. For this purpose, also the esquires had their tourneys separate and distinct from those of the knights. They were usually solemnized on the eve of the more formal and splendid tournaments, in which the knights themselves displayed their valour; and lighter weapons, than those of the knights, though of the same kind, were employed by the esquires. But, as we shall presently notice, the most distinguished among the esquires were (notwithstanding the high authority of the knight of La Mancha to the contrary) frequently admitted to the honours and dangers of the more solemn encounter.

In actual war the page was not expected to render much service, but that of the squire was important and indispensable. Upon a march he bore the helmet and shield of the knight and led his horse of battle, a tall heavy animal fit to bear the weight of a man in armour, but which was led in hand upon a march, while the knight rode an ambling hackney. The squire was also qualified to perform the part of an armourer, not only lacing his master's helmet and buckling his cuirass, but also closing with a hammer the rivets by which the various pieces were united to each other. This was a point of the utmost consequence; and many instances occur of mischances happening to celebrated warriors when the duty was negligently performed.

Chivalry. In the actual shock of battle, the esquire attended closely on the banner of his master, or on his person if he were only a knight bachelor, kept pace with him during the *melée*, and was at hand to remount him when his steed was slain, or relieve him when oppressed by numbers. If the knight made prisoners they were the charge of the esquire; if the esquire himself fortune to make one, the ransom belonged to his master.

On the other hand, the knights who received these important services from their esquires, were expected to display towards them that courteous liberality which made so distinguished a point of the chivalrous character. Lord Audley led the van of the Black Prince's army at the battle of Poitiers, attended by four squires who had promised not to fail him. They distinguished themselves in the front of that bloody day, leaving such as they overcame to be made prisoners by others, and ever pressing forwards where resistance was offered. Thus they fought in the chief of the battle until Lord James Audley was sorely wounded, and his breath failed him. At the last, when the battle was gained, the four faithful esquires bore him out of the press, disarmed him, and staunched and dressed his wounds as they could. As the Black Prince called for the man to whom the victory was in some measure owing, Lord Audley was borne before him in a litter, when the prince, after having awarded to him the praise and renown above all others who fought on that day, bestowed on him five hundred marks of yearly revenue, to be assigned out of his heritage in England. Lord Audley accepted of the gift with due demonstration of gratitude; but no sooner was he brought to his lodging than he called before him the four esquires by whom he had been so gallantly seconded, and the nobles of his lineage, and informed his kinsmen, "Sirs, it hath pleased my Lord the Prince to bestow on me five hundred marks of heritage of which I am unworthy, for I have done him but small service. Behold, Sirs, these four squires, which have always served me truly, and specially this day; the honour that I have is by their valour. Therefore I resign to them and their heirs forever, in like manner as it was given to me, the noble gift which the Prince hath assigned me." The lords beheld each other, and agreed it was a proof of great chivalry to bestow so royal a gift, and gladly undertook to bear witness to the transfer. When Edward heard these tidings, he sent for Lord Audley, and desired to know why he had bestowed on others the gift he had assigned him, and whether it had not been acceptable to him: "Sir," said Lord Audley, "these four squires have followed me well and truly in several severe actions, and at this battle they served me so well, that had they done nothing else, I had been bound to reward them. I am myself but a single man, but, by aid of their united strength and valour, I was enabled to execute the vow which I had made to give the onset in the first battle in which the King of England or his sons should be pre-

Chivalry. sent, and had it not been for them, I must have been left dead on the field. This is the reason I have transferred your Highnesses bounty, as to those by whom it was best deserved." The Black Prince not only approved of and confirmed Lord Audley's grant, but conferred upon him, not to be outdone in generosity, an yearly revenue of six hundred marks more, for his own use. * The names of the esquires, who thus distinguished themselves, and experienced such liberality at the hands of their leader, were Delves of Doddington, Dutton of Dutton, Fowlshurst of Crewe, and Hawkestone of Wreynhill, all Cheshire families. This memorable instance may suffice to show the extent of gratitude which the knights entertained for the faithful service of their squires. But it also leads us to consider some other circumstances relating to the order of esquire.

Although, in its primitive and proper sense, the state of esquire was merely preparatory to that of knighthood, yet it is certain that many men of birth and property rested content with attaining that first step; and, though greatly distinguished by their feats of arms, never rose, nor apparently sought to rise, above the rank which it conferred. It does not appear that any of the esquires of Lord Audley were knighted after the battle of Poitiers, although there can be no doubt that their rank, as well as their exploits, entitled them to expect that honour. The truth seems to be, that it may frequently have been more convenient, and scarcely less honourable, to remain in the unenvied and unpretending rank of esquire, than to aspire to that of knighthood, without a considerable fortune to supply the expences of that dignity. No doubt, in theory, the simplest knight bachelor was a companion, and in some degree equal, with princes. But, in truth, we shall presently see, that, where unsupported by some sort of income to procure suitable equipment and retainers, that dignity was sometimes exposed to ridicule. Many gallant gentlemen, therefore, remained esquires, either attached to the service of some prince or eminent nobleman, or frequently in a state of absolute independence, bringing their own vassals to the field, whom, in such cases, they were entitled to muster under a *Penoncelle*, or small triangular streamer, somewhat like the naval pendant of the present day. The reader of history is not, therefore, to suppose, that, where he meets with an esquire of distinguished name, he is therefore, necessarily, to consider him as a youthful candidate for the honour of knighthood, and attending upon some knight or noble. This is, indeed, the primitive, but not the uniform meaning of the title. So many men of rank and gallantry appear to have remained esquires, that, by degrees, many of the leading distinctions between them and the knights were relaxed or abandoned. In Froissart's *Chronicles*, we find that esquires frequently led independent bodies of men, and, as we have before hinted, mingled with the knights in the games of chivalry; the difference chiefly consisting in title, precedence, the shape of the flag under which they arrayed their

Chivalry. followers, and the fashion of their armour. The esquires were permitted to bear a shield, emblazoned, as we have already seen, with armorial bearings. There seems to have been some difference in the shape of the helmet; and the French esquire was not permitted to wear the complete hauberk, but only the shirt of mail, without hood or sleeves. But the principal distinction between the independent esquire (terming him such who was attached to no knight's service) and the knight, was the spurs, which the esquire might wear of silver, but by no means gilded.

To return to the esquires most properly so termed, their dress was, during their period of probation, simple and modest, and ought regularly to have been made of brown, or some other uniform and simple colour. This was not, however, essential. The garment of Chaucer's squire was embroidered like a meadow. The petit Jehan de Saintré was supplied with money by his mistress to purchase a silken doublet and embroidered hose. There is also a very diverting account in the *Memoirs of Bertrand de Guesclin* of the manner in which he prevailed on his uncle, a covetous old churchman, to assign him money for his equipment on some occasion of splendour. We may therefore hold, that the sumptuary laws of squirehood were not particularly attended to, or strictly enforced.

A youth usually ceased to be a page at fourteen, or a little earlier, and could not regularly receive the honour of knighthood until he was one and twenty. But, if their distinguished valour anticipated their years, the period of probation was shortened. Princes of the blood royal, also, and other persons of very high eminence, had this term abridged, and sometimes so much so as to throw a ridicule upon the order of knighthood, by admitting within "the temple of honour," as it was the fashion of the times to call it, children who could neither understand nor discharge the duties of the office to which they were thus prematurely called.

The third and highest rank of chivalry was that of Knights. In considering this last dignity, we shall first inquire, how it was conferred; secondly, the general privileges and duties of the order; thirdly, the peculiar ranks into which it was finally divided, and the difference betwixt them.

Knighthood was, in its origin, an order of a republican, or at least an oligarchic nature; arising, as has been shown, from the customs of the free tribes of Germany, and, in its essence, not requiring the sanction of a monarch. On the contrary, each knight could confer the order of knighthood upon whomsoever preparatory noviciate and probation had fitted to receive it. The highest potentates sought the *accolade*, or stroke which conferred the honour, at the hands of the worthiest knight whose achievements had dignified the period. Thus Francis I. requested the celebrated Bayard, the *Good Knight without reproach or fear*, to make him; an honour which Bayard valued so highly, that, on sheathing his sword, he vowed never more

Chivalry. to use that blade, except against Turks, Moors, and Saracens. The same principle was carried to extravagance in a romance, where the hero is knighted by the hand of Sir Lancelot of the Lake, when dead. A sword was put into the hand of the skeleton, which was so guided as to let it drop on the neck of the aspirant. In the time of Francis I. it had already become customary to desire this honour at the hands of greatness rather than valour, so that the King's request was considered as an appeal to the first principles of chivalry. In theory, however, the power of creating knights was supposed to be inherent in every one who had reached that dignity. But it was natural that the soldier should desire to receive the highest military honour from the general under whose eye he was to combat, or from the prince or noble at whose court he passed as page and squire through the gradations of his noviciate. It was equally desirable, on the other hand, that the prince or noble should desire to be the immediate source of a privilege so important. And thus, though no positive regulation took place on the subject, ambition on the part of the aspirant, and pride and policy on that of the sovereign princes and nobles of high rank, gradually limited to the latter the power of conferring knighthood, or drew at least an unfavourable distinction between the knights dubbed by private individuals, and those who, with more state and solemnity, received the honoured title at the hand of one of high rank. Indeed, the change which took place respecting the character and consequences of the ceremony, naturally led to a limitation in the right of conferring it. While the order of knighthood merely implied a right to wear arms of a certain description, and to bear a certain title, there could be little harm in entrusting, to any one who had already received the honour, the power of conferring it on others. But when this highest order of chivalry conferred not only personal dignity, but the right of assembling under the banner, or pennon, a certain number of soldiers, when knighthood implied not merely personal privileges, but military rank, it was natural that sovereigns should use every effort to concentrate the right of conferring such distinction in themselves, or their immediate delegates. And latterly it was held, that the rank of knight only conferred those privileges on such as were dubbed by sovereign princes.

The times and place usually chosen for the creation of knights, was favourable to the claim of the sovereigns to be the proper fountain of chivalry. Knights were usually made either on the eve of battle, or when the victory had been obtained; or they were created during the pomp of some solemn warning or grand festival. In the former case, the right of creation was naturally referred to the general or prince who led the host; and, in the latter, to the sovereign of the court where the festival was held. The forms in these cases were very different.

When knights were made in the actual field of battle, little solemnity was observed, and the form was probably the same with which private individuals had, in earlier times, conferred the honour on each other. The novice, armed at all points, but without helmet, sword, and spurs, came before the prince or general, at whose hands he was to receive knighthood, and kneeled down, while two persons of dis-

Chivalry. tinction, who acted as his godfathers, and were supposed to become pledges for his being worthy of the honour to which he aspired, buckled on his gilded spurs, and belted him with his sword. He then received the accolade, a slight blow on the neck, with the flat of the sword, from the person who dubbed him, who, at the same time, pronounced a formula to this effect: "I dub thee, knight, in the name of God and St Michael (or in the name of the Father, Son, and Holy Ghost). Be faithful, bold, and fortunate." The new made knight had then only to take his place in the ranks of war, and endeavour to distinguish himself by his forward gallantry in the approaching action, when he was said to win his spurs. It is well known, that, at the battle of Cressy, Edward III. refused to send succours to the Black Prince, until he should hear that he was wounded or dismounted, being determined he should, on that memorable day, have full opportunity to win his spurs. It may be easily imagined, that, on such occasions, the courage of the young knights was wound up to the highest pitch, and, as many were usually made at the same time, their gallantry could not fail to have influence on the fortune of the day. At the siege of Tholouse (1159), Henry II. of England made thirty knights at once, one of whom was Malcolm IV. King of Scotland. Even, on these occasions, the power of making knights was not understood to be limited to the commander in chief. At the fatal battle of Homildown, in 1401, Sir John Swinton, a warrior of distinguished talents, observing the slaughter made by the English archery, exhorted the Scots to rush on to a closer engagement. Adam Gordon, between whose family and that of Swinton a deadly feud existed, hearing this sage council, knelt down before Swinton, and prayed him to confer on him the honour of knighthood, which he desired to receive from the wisest and boldest knight in the host. Swinton conferred the order; and they both rushed down upon the English host followed only by a few cavalry. If they had been supported the attack might have turned the fate of the day. But none followed their gallant example, and both champions fell. It need hardly be added, that the commander, whether a sovereign prince or not, equally exercised the privilege of conferring knighthood. In the old ballad of the battle of Otterburn, Douglas boasts that, since he had entered England, he had

"With brand dubb'd many a knight."

But it was not in camps and armies alone that the honours of knighthood were conferred. At the *Cour Plénière*, a high court to which sovereigns summoned their crown vassals at the solemn festivals of the church, at the various occasions of solemnity which occurred in the royal family, from marriage, birth, baptism, and the like, the monarch was wont to confer on novices in chivalry its highest honour, and the ceremonies used on such investiture added to the dignity of the occasion. It was then that the full ritual was observed which, on the eve of battle, was necessarily abridged or omitted. The candidates watched their arms all night in a church or chapel, and prepared for the honour to be conferred on them, by vigil, fast, and prayer. They were solemnly divested of the brown frock, which was the appropriate

Chivalry. dress of the squire, and having been bathed, as a symbol of purification of heart, they were attired in the richer garb appropriate to knighthood. They were then solemnly invested with the appropriate arms of a knight; and it was not unusual to call the attention of the novice to a mystical or allegorical explanation of each piece of armour as it was put on. These exhortations consisted in strange and extravagant parallels betwixt the temporal and spiritual state of warfare, in which the metaphor was hunted down in every possible shape. The under dress of the knight was a close jacket of chamois leather, over which was put the mail shirt, composed of rings of steel artificially fitted into each other, as is still the fashion in some parts of Asia. A suit of plate armour was put on over the mail shirt, and the legs and arms were defended in the same manner. Even this accumulation of defensive armour, was by some thought insufficient. In the combat of the Infantes of Carrion with the champions of the Cid, one of the former was yet more completely defended, and to little purpose.

Onward into Ferrand's breast, the lance's point is driven
Full upon his breastplate, nothing would avail;
Two breastplates Ferrand wore, and a coat of mail,
The two are riven in sunder, the third stood him in steal,
The mail sunk in his breast, the mail and the spear head;
The blood burst from his mouth, that all men thought him dead.*

The novice being accoutred in his knightly armour, but without helmet, sword, and spurs, a rich mantle was flung over him, and he was conducted in solemn procession to the church or chapel in which the ceremony was to be performed, supported by his godfathers, and attended with as much pomp as circumstances admitted. High mass was then said, and the novice, advancing to the altar, received from the sovereign the accolade. The churchman present, of highest dignity, often belted on his sword, which, for that purpose, had been previously deposited on the altar, and the spurs were sometimes fastened on by ladies of quality. The oath of chivalry was then taken, to be loyal to God, the king, and the ladies. Such were the outlines of the ceremony, which, however, was varied according to circumstances. A king of Portugal knighted his son in presence of the dead body of the Marquis of Marialva, slain in that day's action, and impressively conjured the young prince to do his duty in life and death like the good knight who lay dead before him. Alms to the poor, largesses to the heralds and minstrels, a liberal gift to the church, were necessary accompaniments to the investiture of a person of rank. The new made knight was conducted from the church with music and acclamations, and usually mounted his horse and executed some curvets in presence of the multitude, couching his lance, and brandishing it as if impatient to open his knightly career. It was at such times, also, that the most splendid tournaments were executed, it being expected that the young knights would display the utmost efforts to

distinguish themselves. Such being the solemnities with which knighthood was conferred, it is no wonder that the power of conferring it should, in peace as well as in war, be almost confined to sovereign princes, or nobles who nearly equalled them in rank and independence. By degrees these restrictions were drawn more and more close, and at length it was held that none but a sovereign or a commander-in-chief, displaying the royal banner, and vested with plenary and vice-regal authority, could confer the degree of knighthood. Queen Elizabeth was particularly jealous of this part of her prerogative, and nothing more excited her displeasure and indignation against her favourite Essex, than the profuseness with which he distributed the honour at Cadiz, and afterwards in Ireland. These anecdotes, however, belong to the decay of chivalry.

The knight had several privileges of dignity and importance. He was associated into a rank wherein kings and princes were in one sense only his equals. He took precedence in war and in counsel, and was addressed by the respectful title of *Messire* in French and *Sir* in English, and his wife by that of *Madame* and *Dame*. A knight was also, in point of military rank, qualified to command any body of men under a thousand. His own service was performed on horseback and in complete armour, of many various fashions, according to the taste of the warriors and the fashion of the age. Chaucer has enumerated some of these varieties.

"With him ther wenten knyghts many on.
Som wol ben armed in an habergeon,
And in a brest plate, and in a gipon;
And som wol have a pair of plates large;
And som wol have a pruse shield, or a targe;
Some wol ben armed on his legges welc,
And have an axe, and some a mace of stele.
Ther n'is no newe guise, that it n'as old.
Armed they weren, as I have you told,
Everich after his opinion."

The weapons of offence, however, most appropriate to knighthood were the lance and sword. They had frequently a battle axe or mace at their saddlebow, a formidable weapon even to men sheathed in iron like themselves. The knight had also a dagger which he used when at close quarters. It was called the dagger of mercy, probably because, when unsheathed, it behoved the antagonist to crave mercy or to die. The management of the lance and of the horse was the principal requisite of knighthood. To strike the foeman either on the helmet or full upon the breast with the point of the lance, and at full speed, was accounted perfect practice; to miss him, or to break a lance across, i. e. athwart the body of the antagonist, without striking him with the point, was accounted an awkward failure; to strike his horse, or to hurt his person under the girdle, was conceived a foul or felon action, and could only be excused by the hurry of a general encounter. When the knights, from the nature of the ground, or other circumstances, alighted to fight on foot, they used to cut some part from the length of their spears, in order to render them more manage-

* See Translations from the Spanish metrical Romance on the subject of the Cid appended to Mr Southey's Cid.

Chivalry.

able, like the pikes used by infantry. But their most formidable onset was when mounted and "in host." They seem then to have formed squadrons not unlike the present disposition of cavalry in the field,—their squires forming the rear-rank, and performing the part of *serrefiles*. As the horses were trained in the tourneys and exercises to run upon each other without flinching, the shock of two such bodies of heavy-armed cavalry was dreadful, and the event usually decided the battle; for, until the Swiss showed the superior steadiness which could be exhibited by infantry, all great actions were decided by the men at arms. The yeomanry of England, indeed, formed a singular exception; and, from the dexterous use of the long bow, to which they were trained from infancy, were capable of withstanding and destroying the mail-clad chivalry both of France and Scotland. Their shafts, according to the exaggerating eloquence of a monkish historian, Thomas of Walsingham, penetrated steel coats from side to side, transfixed helmets, and even splintered lances and pierced through swords! But, against every other pedestrian adversary, the knights, squires, and men-at-arms had the most decided advantage, from their impenetrable armour, the strength of their horses, and the fury of their onset. To render success yet more certain, and attack less hazardous, the horse, on the safety of which the riders so much depended, was armed *en-barbe*, as it was called, like himself. A masque made of iron covered the animal's face and ears; it had a breast-plate, and armour for the croupe. The strongest horses were selected for this service; they were generally stallions, and to ride a mare was reckoned base and unknighly.

To distinguish him in battle, as his face was hid by the helmet, the knight wore above his armour a surcoat, as it was called, like a herald's coat, on which his arms were emblazoned. Others had them painted on the shield, a small triangular buckler of light wood, covered with leather, and sometimes plated with steel, which, as best suited him, the knight could either wield on his left arm, or suffer to hang down from his neck, as an additional defence to his breast, when the left hand was required for the management of the horse. The shape of these shields is preserved, being that on which heraldic coats are most frequently blazoned. But it is something remarkable, that no one of those *heater* shields has been preserved in the Tower, or, so far as we know, in any English collection. The helmet was surmounted by a crest, which the knight adopted after his own fancy. There was deadly offence taken if one knight, without right, assumed the armorial bearings of another; and history is full of disputes on that head, some of which terminated fatally. The heralds were the persons appealed to on these occasions, when the dispute was carried on in peace, and hence flowed the science, as it was called, of heraldry, with all its fantastic niceties. By degrees the crest and device became also hereditary, as well as the bearings on the shield. In addition to his armorial bearings, the knight distinguished himself in bat-

Chivalry.

tle by shouting out his war-cry, which was echoed by his followers. It was usually the name of some favourite saint; united with that of his own family. If the knight had followers under his command, they re-echoed his war-cry, and rallied round his pennon or flag at the sound. The pennon differed from the penoncel, or triangular streamer which the squire was entitled to display, being double the breadth, and indented at the end like the tail of a swallow. It presented the appearance of two penoncels united at the end next the staff, a consideration which was not perhaps out of view in determining its shape. Of course, the reader will understand that those knights only displayed a pennon who had retainers to support and defend it, the mounting this ensign being a matter of privilege, not of obligation.

Froissart's heart never fails to overflow when he describes the encounter of a body of men at arms, arrayed in the manner we have described; he dwells with enthusiasm on the leading circumstances. The waving of banners and pennons, the dashing of spurs into the sides of chargers, and their springing forward to battle; the glittering of armour, the glancing of plumes, the headlong shock and splintering of the lances, the swords flashing though the dust over the heads of the combatants, the thunder of the horses' feet and the clash of armour, mingled with the war-cry of the combatants and the groans of the dying, form the mingled scene of tumult, strife, and death, which the Canon has so frequently transferred to his chivalrous pages.

It was not in war alone that the adventurous knight was to acquire fame. It was his duty, as we have seen, to seek adventures throughout the world, whereby to exalt his own fame and the beauty of his mistress, which inspired such deeds. In our remarks upon the general spirit of the institution, we have already noticed the frantic enterprizes which were seriously undertaken and punctually executed by knights desirous of a name. On these occasions, the undertaker of so rash an enterprize often owed his life to the sympathy of his foes, who had great respect for any one engaged in the discharge of a vow of chivalry. When Sir Robert Knowles passed near Paris, at the head of an English army, in the reign of Edward III., the following remarkable incident took place:

"Now it happened, one Tuesday morning, when the English began to decamp, and had set fire to all the villages wherein they were lodged, so that the fires were distinctly seen from Paris, a knight of their army, who had made a vow, the preceding day, that he would advance as far as the barriers and strike them with his lance, did not brook his oath, but set off with his lance in his hand, his target on his neck, and completely armed except his helmet, and, spurring his steed, was followed by his squire on another courser, carrying the helmet. When he approached Paris, he put on the helmet, which his squire laced behind. He then galloped away, sticking spurs into his horse, and advanced prancing

Chivalry.

to strike the barriers. They were then open, and the lords and barons within imagined he intended to enter the town; but he did not so mean, for having struck the gates according to his vow, he checked his horse and turned about. The French knights who saw him thus retreat, cried out to him, 'Get away! get away! thou hast well acquitted thyself.' As for the name of this knight, I am ignorant of it, nor do I know from what country he came; but he bore for his arms gules à deux foussees noir, with une bordure noir non endentée.

"However, an adventure befel him, from which he had not so fortunate an escape. On his return he met a butcher on the pavement in the suburbs, a very strong man, who had noticed him as he had passed him, and who had in his hand a very sharp and heavy hatchet with a long handle. As the knight was returning alone, and in a careless manner, the valiant butcher came on one side of him, and gave him such a blow between the shoulders, that he fell on his horse's neck: he recovered himself, but the butcher repeated the blow on his head, so that the axe entered it. The knight, through excess of pain, fell to the earth, and the horse galloped away to the squire, who was waiting for his master in the fields at the extremity of the suburbs. The squire caught the courser, but wondered what was become of his master; for he had seen him gallop to the barriers, strike them, and then turn about to come back. He therefore set out to look for him; but he had not gone many paces before he saw him in the hands of four fellows, who were beating him as if they were hammering on an anvil. This so much frightened the squire, that he dared not advance further, for he saw he could not give him any effectual assistance; he therefore returned as speedily as he could.

"Thus was this knight slain: and those lords who were posted at the barriers had him buried in holy ground. The squire returned to the army, and related the misfortune which had befallen his master. All his brother-warriors were greatly displeased thereat." (Johnes's *Froissart*, Vol. II. p. 63.)

An equally singular undertaking was that of Galeazzo of Mantua, as rehearsed by the venerable Doctor Paris de Puteo, in his treatise *De Duello et re Militari*, and by Brantome in his *Essay on Duels*. Queen Joan of Naples, at a magnificent feast given in her castle of Gaeta, had given her hand to Galeazzo, for the purpose of opening the ball. The dance being finished, the gallant knight kneeled down before his royal partner, and, in order to make fitting acknowledgment of the high honour due him, took a solemn vow to wander through the world wherever deeds of arms should be exercised, and not to rest until he had subdued two valiant knights, and had presented them prisoners at her royal footstool, to be disposed of at her pleasure. Accordingly, after a year spent in visiting various scenes of action in Brittany, England, France, Burgundy, and elsewhere, he returned like a falcon with his prey in his clutch, and presented two prisoners of knightly rank to Queen Joan. The queen received the gift very graciously; and, declining to avail herself of the right she had to impose rigorous conditions on the captives, she gave them liberty without ransom,

Chivalry.

and bestowed on them, over and above, several marks of liberality. For this she is highly extolled by Brantome and Dr Paris, who take the opportunity of censuring the very opposite conduct of the Canons of Saint Peter's Church at Rome, upon whom a certain knight had bestowed a prisoner taken in single combat. These ungracious churchmen received the gift as if it had been that of a wild beast for a menagerie, permitting the poor captive the freedom of the church indeed, but prohibiting him to go one step beyond the gate. In which condition, worse than death, they detained the vanquished knight for some time, and were justly blamed, as neither understanding Christian charity nor gentleman-like courtesy.

We return to consider the duties of a knight. His natural and proper element was war. But in time of peace when there was no scope for the fiery spirit of chivalry, the knights attended the tournaments proclaimed by different princes, or, if these amusements did not occur, they themselves undertook feats of arms, to which they challenged all competitors. The nature of these challenges will be best understood from an abridged account of the *pas d'armes*, called the *Justs* of Saint Inglebert, or Sandying fields. This emprise was sustained by three gallant knights of France, Boucicaut, Reynold de Roy, and Saint Py or Saimpi. Their articles bound them to abide thirty days at Saint Inglebert, in the marches of Calais, there to undertake the encounter of all knights and squires, Frenchmen, or strangers, who should come hither, for the breaking of five spears, sharp, or with rockets, at their pleasure. On their lodgings they hung two shields called of peace and war, with their armorial blazons on each. The stranger desiring to just was invited to come or send, and touch which shield he would. The weapons of courtesy were to be employed if he chose the shield of peace, if that of war, the defenders were to give him the desired encounter with sharp weapons. The stranger knights were invited to bring some nobleman with them, to assist in judging the field, and the proclamation concludes with an entreaty to knights and squires strangers, that they will not hold this offer as made for any pride, hatred, or ill-will; but only that the challengers do it to have their honourable company and acquaintance, which, with their whole heart, they desire. They were assured of a fair field, without fraud or advantage; and it was provided, that the shields used should not be covered with iron or steel. The French King was highly joyful of this gallant challenge (although some of his council doubted the wisdom of permitting it to go forth), and exhorted the challengers to regard the honour of their prince and realm, and spare no cost at the solemnity, for which he was willing to contribute ten thousand franks. A number of knights and squires came from England to Calais to accept this gallant invitation; and at the entrance of the "fresh and joly month of May," the challengers pitched three green pavilions in a fair plain between Calais and the Abbey of Saint Inglebert. Two shields hung before each pavilion, with the arms of the owner.

"On the 21st of the month of May, as it had been proclaimed, the three knights were properly armed

Chivalry. and their horses properly saddled, according to the laws of the tournament. On the same day, those knights who were in Calais sallied forth, either as spectators or tilters, and, being arrived at the spot, drew up on one side. The place of the tournament was smooth, and green with grass.

"Sir John Holland was the first who sent his squire to touch the war-target of Sir Boucicaut, who instantly issued from his pavilion completely armed. Having mounted his horse, and grasped his spear, which was stiff and well steeled, they took their distances. When the two knights had for a short time eyed each other, they spurred their horses, and met full gallop with such a force that Sir Boucicaut pierced the shield of the Earl of Huntingdon, and the point of his lance slipped along his arm, but without wounding him. The two knights, having passed, continued their gallop to the end of the list. This course was much praised. At the second course, they hit each other slightly, but no harm was done; and their horses refused to complete the third.

"The Earl of Huntingdon, who wished to continue the tilt, and was heated, returned to his place, expecting that Sir Boucicaut would call for his lance; but he did not, and showed plainly he would not that day tilt more with the earl. Sir John Holland, seeing this, sent his squire to touch the war-target of the Lord de Saimpi. This knight, who was waiting for the combat, sallied out from his pavilion, and took his lance and shield. When the earl saw he was ready, he violently spurred his horse, as did the Lord de Saimpi. They couched their lances, and pointed them at each other. At the onset, their horses crossed; notwithstanding which, they met; but by this crossing, which was blamed, the earl was unhelmed. He returned to his people, who soon rehelled him; and having resumed their lances, they met full gallop, and hit each other with such a force in the middle of their shields, they would have been unhorsed had they not kept tight seats by the pressure of their legs against their horses' sides. They went to the proper places, where they refreshed themselves, and took breath.

"Sir John Holland, who had a great desire to shine at this tournament, had his helmet braced, and re-grasped his spear; when the Lord de Saimpi, seeing him advance on the gallop, did not decline meeting, but, spurring his horse on instantly, they gave blows on their helmets, that were luckily of well-tempered steel, which made sparks of fire fly from them. At this course, the Lord de Saimpi lost his helmet; but the two knights continued their career, and returned to their places.

"This tilt was much praised, and the English and French said, that the Earl of Huntingdon, Sir Boucicaut, and the Lord de Saimpi, had excellently well justed, without sparing or doing themselves any damage. The Earl wished to break another lance in honour of his lady, but it was refused him. He then quitted the lists to make room for others, for he had run his six lances with such ability and courage as gained him praise from all sides." (Johnes's *Froissart*, Vol. IV. p. 143.)

The other justs were accomplished with similar spirit. Sir Peter Courtney, Sir John Russell, Sir Pe-

ter Sherburn, Sir William Clifton, and other English knights, sustaining the honour of their country against the French, who behaved with the greatest gallantry; and the whole was regarded as one of the most gallant enterprizes which had been fulfilled for some time.

Besides these dangerous amusements, the unsettled and misruled state of things during the feudal times, found a gentle knight anxious to support the oppressed and to put down injustice, and, agreeably to his knightly vow, frequent opportunities to exercise himself in the use of arms. There was everywhere to be found oppressors to be chastised, and evil customs to be abolished, and the knight's occupation not only permitted, but actually bound him to volunteer his services in such cases. We shall err greatly if we suppose that the adventures told in romance, are as fictitious as its magic, its dragons, and its fairies. The machinery was indeed imaginary, or rather like that of Homer, it was grounded on the popular belief of the times. But the turn of incidents resembled, in substance, those which passed almost daily under the eye of the narrator. Even the stupendous feats of prowess displayed by the heroes of these tales, against the most overwhelming odds, were not without parallel in the history of the times. When men fought hand to hand, the desperate exertions of a single champion well mounted and armed in proof, was sometimes sufficient to turn the fate of a disputed day, and the war-cry of a well known knight, struck terror further than his arms. The advantage possessed by such an invulnerable champion over the half-naked infantry of the period, whom he might pursue and cut down at his pleasure, was so great that, in the insurrection of the peasants called the *Jacquerie*, the Earl of Foix and the Captal de Buche, their forces not being nearly as one to ten, hesitated not to charge these disorderly insurgents with their men at arms, and were supposed to have slain nearly seven thousand, following the execution of the fugitives with as little mercy as the peasants had showed during the brief success of their rebellion.

The right which crown-vassals claimed and exercised of imposing exorbitant tolls and taxes within their domains, was often resisted by the knights errant of the day, whose adventures, in fact, approached much nearer to those of Don Quixote than perhaps our readers are aware of. For although the knight of La Mancha was, perhaps, two centuries too late in exercising his office of redresser of wrongs, and although his heated imagination confounded ordinary objects with such as were immediately connected with the exercise of chivalry, yet at no great distance from the date of the inimitable romance of Cervantes, real circumstances occurred, of a nature nearly as romantic as the achievements which Don Quixote aspired to execute. In the more ancient times, the wandering knight could not go far without finding some gentleman oppressed by a powerful neighbour, some captive immured in a feudal dungeon, some orphan deprived of his heritage, some traveller pillaged, some convent or church violated, some lady in need of a champion, or some prince engaged in a war with a powerful adversary, all of which incidents

Chivalry.

furnished fit occasion for the exercise of his valour. By degrees, as order became more generally established, and the law of each state began to be strong enough for the protection of the subject, the interference of these self-authorized and self-dependent champions, who besides were, in all probability, neither the most judicious or moderate, supposing them to be equitable, mediators, became a nuisance rather than an assistance to civil society; and undoubtedly this tended to produce those distinctions in the order of knighthood which we are now to notice.

Different Orders of Knighthood.

The most ancient, and originally the sole order of knighthood, was that of the Knight Bachelor. This was the proper degree conferred by one knight on another, without the interference either of prince, noble, or churchman, and its privileges and duties approached nearly to those of the knight-errant. Were it possible for human nature to have acted up to the pitch of merit required by the statutes of chivalry, this order might have proved for a length of time a substitute for imperfect policy,—a remedy against feudal tyranny,—a resource for the weak when oppressed by the strong. Unquestionably, in many individual instances, knights were all that we have described them. But the laws of chivalry, like those of the ascetic orders, while announcing an high tone of virtue and self-denial, unfortunately afforded the strongest temptations to those who professed its vows to abuse the character which they assumed. The degree of knighthood was easily attained, and did not subject the warrior on whom it was granted to any particular tribunal in case of his abusing the powers which it conferred. Thus the knight became, in many instances, a wandering and licentious soldier, carrying from castle to castle, and from court to court, the offer of his mercenary sword, and frequently abusing his character to oppress those whom his oath bound him to protect. The licence and foreign vices imported by those who had returned from the crusades, the poverty also to which noble families were reduced by these fatal expeditions, all aided to throw the quality of knight-bachelor lower in the scale of honour, when unsupported by birth, wealth, or the command of followers.

The poorest knight-bachelor, however, long continued to exercise the privileges of the order. Their title of bachelor (or *Bas Chevalier*, according to the best derivation), marked that they were early held in inferior estimation to those more fortunate knights who had extensive lands and numerous vassals. They either attached themselves to the service of some prince or rich noble, and were supported at their expence, or they led the life of mere adventurers. There were many knights, who, like Sir Gaudwin in the romance of *Partenopex de Blois*, subsisted by passing from one court, camp, and tournament, to another, and contrived, even by various means open to persons of that profession, to maintain, at least for a time, a fair and goodly appearance.

So riding, they o'ertake an errant knight
Well harnessed, and large of limb, Sir Gaudwin hight;
He nor of castle nor of land was lord,
Homeless he reap'd the harvest of the sword;
And now not more on fame than profit bent,
Rode with blythe heart unto the tournament,

For cowardice he held it deadly sin,
And sure his mind and bearing were akin.
The face an index to the soul within,
It seem'd that he, such pomp his train bewray'd,
Had shap'd a goodly fortune by his blade;
His knaves were, point device, in livery dight,
With sumpter-nags, and tents for shelter in the night.

Chivalry.

These bachelor knights, as Mr Rose has well described Sir Gaudwin, set their principal store by valour in battle, and perhaps it was the only quality of chivalry which they at all times equally prized and possessed. Their boast was to be the children of war and battle, living in no other atmosphere but what was mingled with the dust of conflict and the hot breath of charging steeds. A "gentle bachelor" is so described in one of the *Fabliaux* translated by Mr Way:

"What gentle bachelor is he,
Sword-begot in fighting field,
Rock'd and cradled in a shield,
Whose infant food a helm did yield."

His resistless gallantry in tournament and battle,—the rapidity with which he traversed land and sea, from England to Switzerland, to be present at each remarkable occasion of action,—with his hardihood in enduring every sort of privation,—and his generosity in rewarding minstrels and heralds,—his life of battle and turmoil,—and his deeds of strength and fame,—are all enumerated. But we hear nothing of his redressing wrongs, or of his protecting the oppressed. The knight-bachelor, according to this picture, was a valiant prize-fighter, and lived by the exercise of his weapons.

In war, the knight-bachelor had an opportunity of maintaining, and even of enriching himself, if fortunate, by the ransom of such prisoners as he happened to make in battle. If, in this way, he accumulated wealth, he frequently employed it in levying followers, whose assistance, with his own, he hired out to such sovereigns as were willing to set a sufficient price on his services. In time of peace, the tournaments afforded, as we have already observed, a certain means of income to these adventurous champions. The horses and arms of the knights who succumbed on such occasions, were forfeited to the victors, and these the wealthy were always willing to reclaim by a payment in money. At some of the achievements in arms, the victors had the right, by the conditions of the encounter, to impose severe terms on the vanquished, besides the usual forfeiture of horse and armour. Sometimes the unsuccessful combatant ransomed himself from imprisonment, or other hard conditions, by a sum of money; a transaction in which the knight-bachelors, such as we have described them, readily engaged. These adventurers used to call the sword which they used in tourneys, their *gagne-pain*, or bread-winner, as itinerant fiddlers of our days denominate their instruments.

Dont i est guigne-pain nommée
Car par li est gagnies li pains.

Pèlerinage du Monde, par Guigneville.

Men of such roving and military habits, subsisting by means so precarious, and lying under little or no restraint from laws, or from the social system, were frequently dangerous and turbulent members of the commonwealth. Every usurper, tyrant, or rebel,

Chivalry. found knights bachelors to espouse his cause in numbers proportioned to his means of expenditure. They were precisely the "landless resolute," whom any adventurer of military fame or known enterprise could easily collect

"For food and diet to some enterprise
That hath a stomach in't."

Sometimes knights were found who placed themselves directly in opposition to all law and good order, headed independent bands of depredators, or, to speak plainly, of robbers, seized upon some castle as a place of temporary retreat, and laid waste the country at their pleasure. In the disorderly reigns of Stephen and of King John, many such leaders of banditti were found in England. And France, in the reign of John and his successors, was almost destroyed by them. Many of these leaders were knights, or squires, and almost all pretended that in their lawless licence they only exercised the rights of chivalry, which permitted, and even enjoined, its votaries to make war without any authority but their own, whenever a fair cause of quarrel occurs.

These circumstances brought the profession of knight bachelor into suspicion, as, in other cases, the poverty of those who held the honour exposed it to contempt in their person. The sword did not always reap a good harvest; an enterprise was unfortunate, or a knight was discomfited. In such circumstances, he was obliged to sell his arms and horse, and endure all the scorn which is attached to poverty. In the beautiful lay of Lanval, and in the corresponding tale of Grucelun, the story opens with the picture of the hero reduced to indigence, dunned by his landlord, and exposed to contempt by his beggarly equipment. And when John de Vienne and his French men at arms, returned from Scotland, disgusted with the poverty and ferocity of their allies, without having had any opportunity to become wealthy at the expence of the English, and compelled before their departure to give satisfaction for the insolencies which they committed towards the inhabitants, "divers knights and squires had passage and so returned, some into Flanders, and as wind and weather would drive them, without horse and harness, right poor and feeble, cursing the day that ever they came into Scotland, saying that never man had so hard a voyage." (Bernier's *Froissart*, Vol. II. (reprint) p. 32.) The frequent prohibition of tournaments, both by the church and by the more peaceful sovereigns, had also its necessary effect in impoverishing the knights bachelors, to whom, as we have seen, these exhibitions afforded one principal means of subsistence. This is touched upon in one of the French *fabliaux*, as partly the cause of the poverty of a chevalier, whose distresses are thus enumerated:

"Lasten gentles, while I tell
How this knight in fortune fell:
Lands nor vineyards had he none,
Justs and war his living won;
Well on horseback could he prance,
Boldly could he break a lance,

Well he knew each warlike use;
But there came a time of truce,
Peaceful was the land around,
Nowhere heard a trumpet sound,
Rust the shield and taulchon had,
Just and tourney were forbid,
All his means of living gone,
Ermine mantle had he none,
And on pawn had long been laid
Cap and mantle of brocade,
Harness rich and charger stout,
All were eat and drunken out."

Chivalry.

As the circumstances which we have mentioned, tended to bring the order of knight bachelor in many instances into contempt, the great and powerful attempted to entrench themselves within a circle which should be inaccessible to the needy adventurers whom we have described. Hence the institution of Knights Banneret was generally received.

The distinction betwixt the knight banneret and the knight bachelor was merely in military rank and precedence, and the former may rather be accounted an institution of policy than of chivalry. The bachelor displayed, or was entitled to display, a pennon or forked ensign. The knight banneret had the right of raising a proper *banner*, from which his appellation was derived. He held a middle rank, beneath the barons or great feudatories of the Crown, and above the knights bachelors. The banner from which he took his title was a flag squared at the end, which however in strictness was oblong, and not an exact square on all the sides, which was the proper emblem of a baton. Du Tillet reports, that the Count de Laval challenged Sir Raoul de Couequeus' right to raise a square banner, being a banneret, and not a baron, and adds, that he was generally ridiculed for this presumption, and called the knight with the square ensign. The circumstance of the encroachment plainly shows, that the distinction was not absolutely settled, nor have we found the ensign of the bannerets anywhere described except as being generally a square standard. Indeed, it was only the pennon of the knight a little altered; for he who aspired to be a banneret received no higher gradation in chivalry, as attached to his person, and was inducted into his new privileges, merely by the commander in chief, upon the eve of battle, cutting off the swallow-tail or forked termination of the pennon.

In the appendix to Joinville's *Memoirs*, there is an essay on the subject of the bannerets, in which the following account of them is quoted from the ancient book of Ceremonies:

"Comme un bachelier peut lever banniere, et devenir banneret.

"Quant un bachelier a grandement servi et suivy la guerre, et que il a assez terre, et que il puisse avoir gentilshommes, ses hommes, et pour accompagner sa banniere, il peut licitement lever banniere, et non autrement. Car nul homme ne doit porter, ne lever banniere en bataille, s'il n'a du moins cinquante hommes d'armes, tous ses hommes et les archiers et arbalestriers qui y appartiennent. Et s'il les a il doit à la première bataille, ou il se trouvera, ap-

* See the original in the republication of Barbazan's *Fabliaux*, Vol. III. p. 410.

Chivalry. porter un pennon de ses armes, et doit venir au connestable, ou aux marischaux, ou a celui qui sera lieutenant de l'ost pour le prince, requirer qu'il porte bannière; et s'il lui octroient, doit sommer les heraux pour tesmoignage, et doivent couper la queue du pennon, et alors le doit porter et lever avant les autres bannières, au dessous des autres barons."

There is this same ceremonial, in a chapter respecting the banneret, in these terms:

"Comme se doit maintenir un banneret en bataille.

"Le banneret doit avoir cinquante lances, et les gens de trait qui y appartiennent: c'est à savoir les xxv. pour lui, et sa bannière garder. Et doit estre sa bannière dessous des barons. Et s'il y a autres bannière ils doivent mettre leurs bannières à l'honneur, chacun selon son endroit, et pareillement tout homme qui porte bannière."

Froissart, always our best and most amusing authority, gives an account of the manner in which the celebrated Sir John Chandos was made banneret by the Black Prince, before the battle of Navarete. The whole scene forms a striking picture of an army of the middle ages moving to battle. Upon the pennons of the knights, penoncels of the squires, and banners of the barons and bannerets, the army formed, or, in modern phrase, dressed its line. The usual word for the attack was, "Advance banners in the name of God and Saint George."

"When the sun was risen, it was a beautiful sight to view these battalions, with their brilliant armour glittering with its beams. In this manner, they nearly approached to each other. The prince, with a few attendants, mounted a small hill, and saw very clearly the enemy marching straight towards them. Upon descending this hill, he extended his line of battle in the plain, and then halted.

"The Spaniards, seeing the English had halted, did the same, in order of battle; then each man tightened his armour, and made ready as for instant combat.

"Sir John Chandos advanced in front of the battalions with his banner uncased in his hand. He presented it to the prince, saying, 'my lord, here is my banner; I present it to you, that I may display it in whatever manner shall be most agreeable to you; for, thanks to God, I have now sufficient lands that will enable me so to do, and maintain the rank which it ought to hold.'

The prince, Don Pedro being present, took the banner in his hands, which was blazoned with a sharp stake gules, on a field argent; after having cut off the tail to make it square, he displayed it, and, returning it to him by the handle, said, 'Sir John, I return you your banner, God give you strength and honour to preserve it.'

"Upon this, Sir John left the prince, went back to his men, with the banner in his hand, 'Gentlemen, behold my banner and yours; you will, therefore, guard it as it becomes you.' His companions, taking the banner, replied with much cheerfulness,

Chivalry. that 'if it pleased God and St George, they would defend it well, and act worthily of it, to the utmost of their abilities.'

"The banner was put into the hands of a worthy English squire, called William Allestry, who bore it with honor that day, and loyally acquitted himself in the service. The English and Gascons soon after dismounted on the heath, and assembled very orderly together, each lord under his banner or pennon, in the same battle array as when they passed the mountains. It was delightful to see and examine these banners and pennons, with the noble army that was under them."

It should not be forgotten, that Sir John Chandos exerted himself so much to maintain his new honour, that, advancing too far among the Spaniards, he was unhorsed, and, having grappled with a warrior of great strength, called Martin Ferrand, he fell undermost, and must have been slain had he not bethought him of his dagger, with which he stabbed his gigantic antagonist. (Johnes's *Froissart*, Vol. I. p. 731.)

A banneret was expected to bring into the field at least thirty men-at-arms, that is, knights or squires mounted, and in complete order, at his own expence. Each man-at-arms, besides his attendants on foot, ought to have a mounted crossbow-man, and a horseman armed with a bow and axe. Therefore, the number of horsemen alone, who assembled under a banner, was at least three hundred, and, including followers on foot, might amount to a thousand men. The banneret might, indeed, have arrayed the same force under a pennon, but his accepting a banner bound him to bring out that number at least. There is no room, however, to believe, that these regulations were very strictly observed.

In the reign of Charles VII., the nobles of France made a remonstrance to the King, setting forth, that their estates were so much wasted by the long and fatal wars with England, that they could no longer support the number of men attached to the dignity of banneret. The companies of men-at-arms, which had hitherto been led by knights of that rank, and the distinction between knights bannerets and knights bachelors, was altogether disused from that period.* In England the title survived, but in a different sense. Those who received knighthood in a field of battle, where the royal standard was displayed, were called knights banneret. Thus, King Edward VI. notices in his *Journal*, that, after the battle of Pinkie, "Mr Brian Sadler and Vane were made bannerets."

The distinction of banneret was not the only sub-division of knighthood. The special privileged fraternities, orders, or associations, of knights, using a particular device, or embodied for a particular purpose, require also to be noticed. These might, in part, be founded upon the union which knights were wont to enter to with each other as "companions in arms," than which nothing was esteemed more sacred. The partners were united for weal and woe, and no crime was accounted more infamous than to desert or betray a companion at arms. They had the same

* See the works of Pasquier, Du Tillet, Le Gendre, and other French antiquaries.

Chivalry. friends and the same foes; and, as it was the genius of chivalry to carry every virtuous and noble sentiment to the most fantastic extremity, the most extravagant proofs of fidelity to this engagement were often exacted or bestowed. The beautiful romance of *Ames and Amelien*, in which a knight slays his own child to make a salve with its blood to cure the leprosy of his brother in arms, turns entirely on this extravagant pitch of sentiment.

To this fraternity only two persons could, with propriety, bind themselves. But the various orders, which had in view particular objects of war, or were associated under the authority of particular sovereigns, were also understood to form a bond of alliance and brotherhood amongst themselves.

The great orders of the Templars and Knights-Hospitallers of Saint John of Jerusalem, as well as that of the Teutonic Knights, were military associations, formed, the former for defence of the Holy Land, and the last for conversion (by the edge of the sword of course) of the pagans in the north of Europe. They were managed by commanders or superintendents, and by a grand master, forming a sort of military republic, the individuals of which were understood to have no distinct property or interest from the order in general. But the system and history of these associations will be found under the proper heads. It is here only necessary to notice them as subdivisions of the knighthood, or chivalry of Europe.

Other subdivisions arose from the various associations, also called orders, formed by the different sovereigns of Europe, not only for the natural purpose of drawing around their persons the flower of knighthood, but often with political views of much deeper import. The romances which were the favourite reading of the time, or which, at least, like the servant in the comedy, the nobles "had read to them," and which were on all occasions quoted gravely, as the authentic and authoritative records of chivalry, afforded the most respectable precedents for the formation of such fraternities under the auspices of sovereign princes; the Round Table of King Arthur, and the Paladins of Charlemagne, forming cases strictly in point. Edward III., whose policy was equal to his love of chivalry, failed not to avail himself of these precedents, not only for the exaltation of military honour and exercise of warlike feats, but unquestionably that he might draw around him, and attach to his person, the most valiant knights from all quarters of Europe. For this purpose, in the year 1344, he proclaimed, as well in Scotland, France, Germany, Hainault, Spain, and other foreign countries, as well as in England, that he designed to revive the Round Table of King Arthur, offering free conduct and courteous reception to all who might be disposed to attend the splendid justs to be held upon that occasion at Windsor Castle. This solemn festival, which Edward proposed to render annual, excited the jealousy of Philip de Valois, king of France, who not only prohibited his subjects to attend the Round Table at Windsor, but proclaimed an opposite Round Table to be held by himself at Paris. In consequence of this interference, the Festival of Edward lost some part of its celebrity, and was

diminished in splendour and frequency of attendance. Chivalry. This induced King Edward to establish the memorable Order of the Garter. Twenty-six of the most noble knights of England and Gascony were admitted into this highly honourable association, the well-known motto of which (*Hon y soit qui mal y pense*) seems to apply to the misrepresentations which the French monarch might throw out respecting the Order of the Garter, as he had already done concerning the festival of the Round Table. There was so much dignity, as well as such obvious policy, in selecting from the whole body of chivalry a select number of champions, to form an especial fraternity under the immediate patronage of the sovereign; it held out such a powerful stimulus to courage and exertion to all whose eyes were fixed on so dignified a reward of ambition, that various orders were speedily formed in the different courts of Europe, each having its own peculiar badges, emblems, and statutes. To enumerate these is the task of the herald, not of the historian, who is only called upon to notice their existence and character. The first effect of these institutions on the spirit of chivalry in general, was doubtless favourable, as holding forth to the knighthood an high and honourable prize of emulation. But when every court in Europe, however petty, had its own peculiar order and ceremonial, while the great potentates established several; these dignities became so common, as to throw into the shade the order of Knights Bachelors, the parent and proper degree of chivalry, in comparison to which the others were mere innovations. The last distinction introduced, when the spirit of chivalry was almost totally extinguished, was the degree of Knight Baronet.

The degree of Baronet, or of hereditary knight-^{Baronet.} hood, might have been, with greater propriety, termed an inferior rank of noblesse, than an order of chivalry. Nothing can be more alien from the original idea of chivalry, than that knighthood could be bestowed on an infant, who could not have deserved the honour, or be capable of discharging its duties. But the way had been already opened for this anomaly, by the manner in which the orders of foreign knighthood had been conferred upon children, and infants in nonage. Some of these honours were also held by right of blood; the Dauphin of France, for example, being held to be born a knight of the Holy Ghost, without creation; and men had already long lost sight of the proper use and purpose of knighthood, which was now regarded and valued only as an honorary distinction of rank, that imposed no duties, and required no qualifications, or period of preliminary noviciate. The creation of this new dignity, as is well known, was a device of James I. to fill those coffers which his folly and profusion had emptied; and although the pretext of a Nova Scotia, or of an Ulster settlement, was used as the apology for the creation of the order, yet it was perfectly understood, that the real value given was the payment of a certain sum of money. The cynical Osborne describes this practice of the sale of honours, which, in their origin, were designed as the reward and pledge of chivalrous merit, with satirical emphasis.

"At this time the honour of knighthood, which antiquity reserved sacred, as the cheapest and readi-

Chivalry. est jewel to present virtue with, was promiscuously laid on any head belonging to the yeomandry (made addle through pride and a contempt of their ancestor's pedigree), that had but a court friend, or money to purchase the favour of the meanest able to bring him into an outward roome, when the king, the fountaine of honour, came downe, and was uninterrupted by other businesse: in which case, it was then usuall for him to grant a commission for the chamberlaine, or some other lord to do it."

Degradation.

Having noticed the mode in which knighthood was conferred, and the various subdivisions of the order in general, it is proper to notice the mode in which a knight might be degraded from his rank. This forfeiture might take place from crimes either actually committed, or presumed by the law of arms. The list of crimes for which a knight was actually liable to degradation corresponded to his duties. As devotion, the honour due to ladies, valour, truth, and loyalty, were the proper attributes of chivalry,—so heresy, insults or oppression of females, cowardice, falsehood, or treason, caused his degradation. And Heraldry, an art which might be said to bear the shield of Chivalry, assigned to such degraded knights and their descendants peculiar bearings, called in Blazonry abatements, though it may be doubted if these were often worn or displayed.

The most common case of a knight's degradation occurred in the appeal to the judgment of God by the single combat in the lists. In the appeal to this awful criterion, the combatants, whether personally concerned, or appearing as champions, were understood, in martial law, to take on themselves the full risk of all consequences. And, as the defendant, or his champion, in case of being overcome, was subjected to the punishment proper to the crime of which he was accused, so the appellant, if vanquished, was, whether a principal or substitute, condemned to the same doom to which his success would have exposed the accused. Whichever combatant was vanquished, he was liable to the penalty of degradation; and, if he survived the combat, the disgrace to which he was subjected was worse than death. His spurs were cut off, close to his heels, with a cook's cleaver; his arms were balled and reversed by the common hangman; his belt was cut to pieces, and his sword broken. Even his horse showed his disgrace, the animal's tail being cut off, close to the rump, and thrown on a dunghill. The death-bell tolled, and the funeral service was said, for a knight thus degraded, as for one dead to knightly honour. And, if he fell in the appeal to the judgment of God, the same dishonour was done to his senseless corpse. If alive, he was only rescued from death to be confined in the cloister. Such, at least, were the strict rules of chivalry, though the courtesy of the victor, or the clemency of the prince, might remit them in favourable cases.

Knights might also be degraded without combat, when convicted of a heinous crime. In Stowe's *Chronicle*, we find the following minute account of the degradation of Sir Andrew Harclay, created Earl of Harclay by Edward II., but afterwards accused of traitorous correspondence with Robert the Bruce, and tried before Sir Anthony Lucy.

"He was ledde to the barre as an earle morthily

Chivalry apparelled, with his sword girt about him. horsed, booted, and spurred, and unto whom Sir Anthony spake in this manner. Sir Andrew (quoth he) the King, for thy valiant service, hath done thee great honour, and made thee Earle of Carlile; since which tyme, thou, as a traytor to thy Lord the King, leddest his people, that shoulde have holpe him at the battell of Heighland, awaie by the county of Copland, and through the earldom of Lancaster, by which meanes, our Lorde the King was discomfited there of the Scottes, through thy treason and false-nesse; whereas, if thou haddest come betimes, he hadde had the victorie: and this treason thou committedst for y^e great summe of golde and silver that thou receivdest of James Dowglas, a Scot, the King's enemy. Our Lord the King will, therefore, that the order of knighthood, by the which thou receivdest all thine honour and worship upon thy bodie, be brought to nought, and thy state undone, that other knights, of lower degree, may after thee beware, and take example truly to serve.

"Then commanded he to hese his spurs from his heeles, then to break his sword over his head, which the King had given him to keepe and defend his land therewith, when he made him earle. After this, he let unclothe him of his furred tabard, and of his hooide, of his coate of armes, and also of his girdle: and when this was done, Sir Anthony sayde unto him, Andrew (quoth he), now art thou no knight, but a knave; and, for thy treason, the King will that thou shalt be hanged and drawne, and thyne head smitten off from thy bodie, and burned before thee, and thy bodie quartered: and thy head being suitten off, afterwarde to be set upon London bridge, and thy foure quarters shall be sent into foure good townes of England, that all other may beware by thee. And as Anthony Lucy hadde sayde, so was it done in all things, on the last date of October."

III. We are arrived at the third point proposed in Decay of our arrangement, the causes, namely, of the decay **Chivalry** and extinction of Chivalry.

The spirit of chivalry sunk gradually under a combination of physical and moral causes; the first arising from the change gradually introduced into the art of war, and the last from the equally great alteration produced by time in the habits and modes of thinking in modern Europe. Chivalry began to dawn in the end of the tenth, and beginning of the eleventh century. It blazed forth with high vigour during the Crusades, which indeed may be considered as exploits of national knight-errantry, or general wars, undertaken on the very principles which actuated the conduct of individual knights adventurers. But its most brilliant period was during the wars between France and England, and it was unquestionably in those kingdoms, that the habit of constant and honourable opposition, unembittered by rancour or personal hatred, gave the fairest opportunity for the exercise of the virtues required from him whom Chaucer terms a very perfect gentle knight. Froissart frequently makes allusions to the generosity exercised by the French and English to their prisoners, and contrasts it with the dungeons to which captives taken in war were consigned, both in Spain and Germany. Yet

Chivalry. both these countries, and indeed every kingdom in Europe, partook of the spirit of Chivalry in a greater or less degree; and even the Moors of Spain caught the emulation, and had their orders of knighthood as well as the Christians. But, even during this splendid period, various causes were silently operating the future extinction of the flame, which blazed thus wide and brightly.

An important discovery, the invention of gunpowder had taken place, and was beginning to be used in war, even when chivalry was in its highest glory. It is said Edward III. had field-pieces at the battle of Cressy, and the use of guns is mentioned even earlier. But the force of gunpowder was long known and used, ere it made any material change in the art of war. The long-bow continued to be the favourite, and it would seem the more formidable missile weapon, for well nigh two centuries after guns had been used in war. Still every successive improvement was gradually rendering the invention of fire arms more perfect, and their use more decisive of the fate of battle. In proportion as they came into general use, the suits of defensive armour began to be less generally worn. It was found, that these cumbrous defences, however efficient against lances, swords, and arrows, afforded no effectual protection against these more forcible missiles. The armour of the knight was gradually curtailed to a light head piece, a cuirass, and the usual defences of men-at-arms. Complete harness was only worn by generals and persons of high rank, and that rather, it would seem, as a point of dignity than for real utility. The young nobility of France, especially, tired of the unwieldy steel coats in which their ancestors sheathed themselves, and adopted the slender and light armour of the German Reiters or mercenary cavalry. They also discontinued the use of the lance; in both cases, contrary to the injunctions of Henry IV. and the opinion of Sully. At length, the arms of the cavalry were changed almost in every particular from those which were proper to chivalry; and as, in such cases, much depends upon outward show and circumstance, the light armed cavalier, who did not carry the weapons, or practice the exercises of knighthood, laid aside, at the same time, the habits and sentiments peculiar to the order.

Another change of vital importance, arose from the institution of the bands of gens-d'armes, or men-at-arms in France, constituted, as we have observed, expressly as a sort of standing army, to supply the place of *bannereots*, bachelors, squires, and other militia of early times. It was in the year 1445, that Charles VII. selected from the numerous chivalry of France, fifteen companies of men-at-arms, called Les Compagnies d'Ordonnance, to remain in perpetual pay and subordination, and to enable the sovereign to dispense with the services of the tumultuary forces of chivalry, which, arriving and departing from the host at pleasure, collecting their subsistence by oppressing the country, and engaging in frequent brawls with each other, rather weakened than aided the cause they professed to support. The regulated companies, which were substituted for these desultory bands,

were of a more permanent and manageable description. Each company contained an hundred men-at-arms, and each man-at-arms was to be what was termed a *lance garnie*, that is, a mounted spearman, with his proper attendants, being four archers and a varlet, called a *constitlier*. Thus, each company consisted of six hundred horse, and the fifteen bands amounted to fifteen thousand cavalry. The charge of national defence was thus transferred from the chivalry of France, whose bold and desperate valour was sometimes rendered useless by their independent wilfulness and want of discipline, to a sort of regular forces, whose officers (a captain, lieutenant, and an ensign in each company) held command, not in virtue of their knighthood or banner-right, but being direct commissions from the crown, as in modern times. At first, indeed, these bands of regulated gens-d'armes were formed of the same materials as formerly, though acting under a new system. The officers were men of the highest rank, the archers, and even the varlets, were men of honourable birth. When the Emperor Maximilian proposed that the French gens-d'armes should attempt to storm Padua, supported by the German lance-knechts or infantry, he was informed by Bayard, that, if the French men-at-arms were employed, they must be supported by those of the Germans, and not by the lance-knechts, because, in the French companies of ordonnance, every soldier was a gentleman. But, in the reign of Charles IX., we find the change natural to such a new order of things, was in complete operation. The king was content to seek, as qualifications for his men-at-arms, personal bravery, strength, and address in the use of weapons, without respect to rank or birth, and, probably, in many instances, men of inferior birth were preferred to fill up the ranks of these regulated bands. Montuc informs us in his *Commentaries*, that he made his first campaign, as an archer, in the Marechal de Foix's company of gens d'armes: "A situation much esteemed in these days, when many nobles served in that capacity. At present, the rank is greatly degenerated." The complaints of the old noblesse, says Mezerai, were not without reason. Mean carabineers, they said, valets and lacquies, were recruited in companies, which were put on the same footing with the ancient corps of gens-d'armes, whose officers were all barons of high rank, and almost every man-at-arms a gentleman by birth. These complaints, joined with the charge against Catharine of Medici, that she had, by the creation of twenty-five new members of the order of Saint Michael, rendered its honours as common as the cockle-shells on the sea-shore, serve to show how early the first rude attempt at establishing a standing and professional army operated to the subversion of the ideas and privileges of chivalry. According to La Noue, it would seem that, in his time, the practice still prevailed of sending youths of good birth to serve as pages in the gens-d'armes; but, from the sort of society with whom they mixed in service of that sort, their natural spirit was rather debased, and rendered vulgar and brutal, than trained to honour and gallantry.

A more fatal cause had, however, been for some

land.

time operating in England as well as France, for the destruction of the system we are treating of. The wars of York and Lancaster in England, and those of the Huguenots and of the League, were of a nature so bitter and rancorous, as was utterly inconsistent with the courtesy, fair play, and gentleness, proper to chivalry. Where different nations are at strife together, their war may be carried on with a certain degree of moderation. "During the foreign wars between France and Spain, especially in Piedmont," says La Noue, "we might often see a body of spears pass a village, where the peasants only interrupted their village dance to offer them refreshments; and, in a little after, a hostile troop receive, from the unoffending and unoffended inhabitants, the same courtesy. The two bodies would meet and fight gallantly, and the wounded of both parties would be transferred to the same village, lodged in the same places of accommodation, receive the same attention, and rest peaceably on each others good faith till again able to take the field." He contrasts this generosity with the miserable oppression of the civil wars, carried on by murdering, burning, and plundering, friend and foe, armed and unarmed, alleging, all the while, the specious watch words of God's honour, the King's service, the Catholic religion, the Gospel, our Country. In the end, he justly observes, "the soldiers become ravenous beasts, the country is rendered desert. wealth is wasted, the crimes of the great become a curse to themselves, and God is displeased." The bloody wars of the Rose in England, the execution of prisoners on each side, the fury and animosity which allowed no plea of mercy or courtesy, were scarce less destructive to the finer parts of the spirit of chivalry in England than those of the Huguenots in France.

But the Civil Wars not only operated in debasing the spirit of chivalry, but in exhausting and destroying the particular class of society from which its votaries were drawn. To be of noble birth was not, indeed, absolutely essential to receiving the honour of knighthood, for men of low descent frequently attained it. But it required a distinguished display of personal merit to raise them out of the class where they were born, and the honours of chivalry were, generally speaking, appropriated to those of fair and gentle parentage. The noble families, therefore, were the source from which chivalry drew recruits; and it was upon the nobles that the losses, proscriptions, and forfeitures, of the Civil Wars chiefly fell. We have seen, that, in France, their poverty occasioned their yielding up the privilege of military command to the disposal of the crown. In England it was, fortunately, not so much the crown as the commons who rose on the ruins of the feudal chivalry. But it is well known, that the Civil Wars had so exhausted the English nobility, as to enable Henry VII. to pass his celebrated statutes against those hosts of retainers, which struck, in fact, at the very root of their power. And, thus, Providence, whose ways bring good out of evil, laid the foundation of the future freedom of England in the destruction of what had long been its most constitutional ground of defence, and, in the

subjugation of that system of chivalry which, having softened the ferocity of a barbarous age, was now to fall into disuse, as too extravagant for an enlightened one. Chivalry.

In fact, it was not merely the changes which had taken place in the constitution of armies and fashion of the fight, nor the degraded and weak state of the nobles, but also, and in a great degree, the more enlightened manners of the times, and the different channels in which enthusiasm and energy were directed, which gradually abolished the sentiments of chivalry. We have seen, that the abstract principles of chivalry were, in the highest degree, virtuous and noble, nay, that they failed by carrying to an absurd, exaggerated, and impracticable point, the honourable duties which they inculcated. Such doctrines, when they fail to excite enthusiasm, become exploded as ridiculous. Men's minds were now awakened to other and more important and complicated exercises of the understanding, and were no longer responsive to the subjects which so deeply interested their ancestors of the middle ages. Science of various kinds had been rekindled in the course of the sixteenth century; the arts had been awakened in a style of perfection unknown even to classical ages. Above all, religion had become the interesting study of thousands, and the innovating doctrines of the Reformers, while hailed with ecstasy by their followers, rejected as abominations by the Catholics, and debated fiercely by both parties, involved the nobility of Europe in speculations very different from the *arrets* of the Court of Love, and demanded their active service in fields more bloody than those of tilt and tournament. When the historians or disputants on either side allude to the maxims of chivalry, it is in terms of censure and ridicule. Yet, if we judge by the most distinguished authorities on either side, the Reformers rejected as sinful what the Catholics were contented to brand as absurd. It is with no small advantage to the Huguenots,—to that distinguished party which produced Sully, D'Aubigné, Coligni, Duplessis-Mornay, and La Noue, that we contrast the moral severity with which they pass censure on the books of chivalry with the licentious flippancy of Brantome, who ridicules the same works, on account of the very virtues which they inculcate. From the books of *Amadis de Gaul*, refining, as he informs us, upon the ancient vanities of *Perceforest*, *Tristan*, *Giron*, &c., La Noue contends the age in which he lived derived the recommendation and practice of incontinence, of the poison of revenge, of neglect of sober and rational duty, desperate blood-thirstiness, under disguise of search after honour, and confusion of public order. "They are the instructions," he says, "of Apollyon, who, being a murderer from the beginning, delighteth wholly in promoting murther." "Of the tournaments," he observes, "that such spectacles, rendering habitual the sight of blows and blood, had made the court of France pitiless and cruel." "Let those," he exclaims, "who desire to feed their eyes with blood, imitate the manner of England, where they exercise their cruelty on brute beasts, bringing in bulls and bears to fight with dogs,

Chivalry. a practice beyond comparison far more lawful than the justs of chivalry." *

It is curious to contrast the opinions of La Noue, a stern and moral reformer, and a skilful and brave soldier as France ever produced, although condemning all war that did not spring out of absolute necessity; with those of Brantome, a licentious courtier, who mixed the popish superstitions, which stood him instead of religion, with a leaven of infidelity and blasphemy. From the opinions he has expressed, and from what he has too faithfully handed down as the manners of his court and age, it is plain that all which was valuable in the spirit of chivalry had been long renounced by the French noblesse. To mark this declension, it is only necessary to run over the various requisites already pointed out as necessary to form the chivalrous character, and contrast them with the opinions held in the end of the sixteenth century, in the court of the descendants of Saint Louis.

The spirit of devotion which the rules of chivalry inculcated, was so openly disavowed, that it was assigned as a reason for preferring the character of Sir Tristram to that of Sir Lancelot, that the former is described in romance as relying, like Mezentius, upon his own arm alone, whereas Lancelot, on engaging in fight, never failed to commend himself to God and the saints, which, in the more modern opinions of the gallants of France, argued a want of confidence in his own strength and valour.

The devotion with which the ancient knights worshipped the fair sex, was held as old-fashioned and absurd as that which they paid to heaven. The honours paid to chastity and purity in the German forests, and transferred as a sacred point of duty to the sons of chivalry, was as little to be found in the court of France, according to Brantome, as the chastity and purity to which it was due. The gross and coarse sensuality which we have seen engrafted upon professions of Platonic sentiment, became finally so predominant, as altogether to discard all marks of sentimental attachment; and from the time of Catherine of Medicis, who trained her maids of honour as courtezans, the manners of the court of France seem to have been inferior in decency to those of a well regulated bagnio. The sort of respect which these ladies were deemed entitled to, may be conjectured from an anecdote given by Lord Herbert of Cherbury, whose own character was formed upon the chivalrous model which was now become obsolete. As he stood in the trenches before a besieged place, along with Balagny, a celebrated duellist of the period, between whom and Lord Herbert some altercation had formerly occurred, the Frenchman, in a bravade, jumped over the entrenchment, and, daring Herbert to follow him, ran towards the besieged place, in the face of a fire of grape and musquetry. Finding that Herbert outran him, and seemed to have no intention of turning back, Balagny was forced to set the example of retreating. Lord Herbert then invited him to an en-

counter upon the old chivalrous point, which had the fairer and more virtuous mistress; to which proposition Balagny replied by a jest so coarse, as made the Englishman retort, that he spoke like a mean debauchee, not like a cavalier and man of honour. As Balagny was one of the most fashionable gallants of his time, and, as the story shows, ready for the most hair-brained achievements, his declining combat upon the ground of quarrel chosen by Lord Herbert, is a proof how little the former love of chivalry accorded with the gallantry of these later days.

Bravery, the indispensable requisite of the *preux chevalier*, continued, indeed, to be held in the same estimation as formerly; and the history of the age gave the most brilliant as well as the most desperate examples of it, both in public war and private encounter. But courage was no longer tempered with the good faith and courtesy,—*La bonta dei gli cavalieri antichi*, so celebrated by Ariosto. There no longer existed those generous knights, that one day bound the wounds of a generous enemy, guided him to a place of refuge, and defended him on the journey, and which, on the next, hesitated not to commit itself in turn to the power of a mortal foe, without fear that he would break the faithful word he had pawned for the safety of his enemy. If such examples occur in the civil wars of France, they were dictated by the generosity of individuals who rose above the vices of their age, and were not demanded, as matters of right, from all who desired to stand well in public opinion. The intercourse with Italy, so fatal to France in many respects, failed not to imbue her nobility with the politics of Machiavel,—the coarse licentiousness of Aretin,—and the barbarous spirit of revenge, which held it wise to seek its gratification, not in fair encounter, but *per ogni modo*, in what manner soever it could be obtained. Duels, when they took place, were no longer fought in the lists, or in presence of judges of the field, but in lonely and sequestered places. Inequality of arms was not regarded, however great the superiority on one side. "Thou hast both a sword and dagger," said Quelus to Antragues, as they were about to fight, "and I have only a sword."—"The more thy folly," was the answer, "to leave thy dagger at home. We came to fight, not to adjust weapons." The duel accordingly went forward, and Quelus was slain, his left hand (in which he should have had his dagger) being shockingly cut in attempting to parry his antagonist's blows without that weapon. The challenged person having a right to choose his weapons, often endeavoured to devise such as should give him a decidedly unfair advantage. Brantome records with applause the ingenuity of a little man, who, being challenged by a tall Gascon, made choice of a gorget so constructed, that his gigantic adversary could not stoop his neck, so as to aim his blows right. Another had two swords forged of a temper so extremely brittle, that, unless used with particular caution, and in a manner to which he daily exercised

* *Discourses, Political and Military*, translated out of the French of La Noue, 1587.

Chivalry.

himself, the blade must necessarily fly in pieces. Both these ingenious persons killed their man with very little risk or trouble, and no less applause, it would seem, than if they had fought without fraud and covine. The seconds usually engaged, and when one of the combatants was slain, his antagonist did not hesitate to assist his comrade in oppressing by odds him who remained. The *little French Lawyer* of Fletcher turns entirely on this incident. By a yet more direct mode of murder, a man challenged to a duel was not always sure that his enemy was not to assassinate him by the assistance of ruffians at the place of rendezvous, of which Brantome gives several instances without much censure. The plighted word of an antagonist by no means insured against treachery to the party to whom it was given. De Rosne, a gentleman well skilled in the practice and discipline of the wars, receiving a challenge from De Fargy, through the medium of a young man, who offered to pledge his word and faith for the fair conduct of his principal—made an answer which Brantome seems to approve as prudential. "I should be unwilling," he replied, "to trust my life upon a pledge on which I would not lend twenty crowns." In many cases no ceremony was used, but the nobles assassinated each other without scruple or hesitation. Brantome gives several stories of the Baron des Vitaux, and terms his detestable murders bold and brave revenges. But it would be endless to quote examples. It is enough to call to the reader's recollection the bloody secret of the massacre of St Bartholomew, which was kept by such a number of the Catholic noblemen for two years, at the expence of false treaties, promises, and perjuries innumerable, and the execution which followed on naked, unarmed, and unsuspecting men, in which so many gallants lent their willing swords.

In England, the free tone of the government, and the advantage of equal laws, administered without respect of persons, checked similar enormities, which however do not appear to have been thought, in all cases, inconsistent with the point of honour, which, if not, as in France, totally depraved from the ancient practices of chivalry, might probably have soon become so. Sir John Ayres did not hesitate to attack Lord Herbert with the assistance of his servants; and the outrage upon the person of Sir John Coventry, which gave rise to the Coventry act against cutting and maiming, evinced the same spirit of degenerate and blood-thirsty revenge. Lord *Sanguhar* having lost an eye in a trial of skill with a master of defence, conceived that his honour required that he should cause the poor man to be assassinated by ruffians in his own school. But as this base action met its just reward at the gallows, the spirit of Italian revenge was probably effectually checked by such a marked example. At the gallows, the unfortunate nobleman expressed his detestation for the crime, which he then saw in all its enormity. Before his trial, he said, the devil had so blinded his understanding, that he could not understand that he had done amiss, or otherwise than befitting a man of high rank and quality, having been trained up to the court, and living the life of a soldier, which sort of men, he said, stood more on a point of honour than religion. The feelings of chivalry must have been indeed degraded, when so base an assassination was

accounted a point of honour. In Scotland, the manners of which country, as is well observed by Robertson, strongly resembled those of France, the number of foul murders during the sixteenth century was almost incredible, and indeed assassination might be termed the most general vice of the sixteenth century.

From these circumstances, the total decay of chivalrous principle is sufficiently evident. As the progress of knowledge advanced, men learned to despise its fantastic refinements; the really enlightened, as belonging to a system inapplicable to the modern state of the world; the licentious, fierce, and subtle, as throwing the barriers of affected punctilio, betwixt them and the safe, ready, and unceremonious gratification of their lust or their vengeance.

The system, as we have seen, had its peculiar advantages during the middle ages. Its duties were not, and indeed could not always be performed in perfection, but they had a strong influence on public opinion, and we cannot doubt that its institutions, virtuous as they were in principle, and honourable and generous in their ends, must have done much good and prevented much evil. We can now only look back on it as a beautiful and fantastic piece of frostwork, which has dissolved in the beams of the sun! But though we look in vain for the pillars, the vaults, the cornices, and the fretted ornaments of the transitory fabric, we cannot but be sensible that its dissolution has left on the soil valuable tokens of its former existence. We do not mean, nor is it necessary to trace, the slight shades of chivalry, which are yet received in the law of England. An appeal to combat in a case of treason, was adjudged in the celebrated case of Ramsay and Lord Reay, in the time of Charles I. An appeal of murder seems to have been admitted as legal within the last year, and is perhaps still under decision. But it is not in such issues, rare as they must be, that we ought to trace the consequences of chivalry. We have already shown, that its effects are rather to be sought in the general feeling of respect to the female sex; in the rules of forbearance and decorum in society; in the duties of speaking truth and observing courtesy; and in the general conviction and assurance, that, as no man can encroach upon the property of another without accounting to the laws, so none can infringe on his personal honour, be the difference of rank what it may, without subjecting himself to personal responsibility. It will be readily believed that, in noticing the existence of duelling as a relic of chivalry, we do not mean to discuss the propriety of the custom. It is our happiness that the excesses to which this spirit is liable, are checked by the laws which wisely discountenance the practice; for although the severity of the laws sometimes give way to the force of public opinion, they still remain an effectual restraint, in every case where the circumstances argue either wanton provocation or unfair advantage. It is to be hoped that, as the custom of appealing to this Gothic mode of settling disputes is gradually falling into disuse, our successors may enjoy the benefit of the general urbanity, decency, and courtesy which it has introduced into the manners of Europe, without having recourse to a remedy, not easily reconciled to law or to Christianity. (N. N.)

Chivalry.

Chromatics.

or CDG, we shall have the deduction required to be made from the length of the path within the plate, since the velocities vary directly as these sines; and by this deduction the secants, AB, BC, will be reduced to the cosines BF, BG: so that the true retardation will always be proportional to the cosine of refraction.

The same demonstration is applicable to the difference of the paths of the two portions of light reflected once only, from the upper and lower surfaces of the plates respectively, supposing A, the point of emergence of the transmitted ray, to become the point of incidence of a new reflected ray HA. Hence it might be expected that all the phenomena of colours should be the same as in the case of transmitted light; and this really appears to happen when the observation is made on a plate of air contained between a transparent substance and a polished surface of gold or silver; or on a plate of a refractive density intermediate between the densities of the neighbouring substances, as in the instance of a thin coat of smoke or of an oxid, adhering to any polished metallic surface, which is at first of a yellowish white, and as it becomes thicker, changes to a yellow and an orange colour: but in more common cases there is a loss of half an interval in one of the two reflections only, so that the thicknesses affording a perfect coincidence, for any species of colour, are always intermediate between the thicknesses affording the same colour by transmission; and hence the tints of the two series of rings are always complementary to each other, the series seen by reflection always beginning from a dark central spot, when they are exhibited by any detached transparent substance, as a soap bubble, a thin film of glass, or of talc, or by a plate of air contained between two plates of glass, or between a plate of glass and a piece of polished steel.

There is a peculiarity in the surface of silver and gold, and perhaps of some other metals, that besides the regular reflection at an angle equal to that of incidence, a considerable quantity of light is dispersed irregularly; and this light, as Mr Arago has observed, is polarised in a direction transverse to that of the usual polarisation by reflection; there is also in the irregular reflection no loss of a half interval; so that it exhibits, with a piece of glass, a series of rings resembling those which are produced by polished steel, except that their dimensions are not reduced exactly in the same proportion by the obliquity of the incidence, because the light which forms them is not required to pass towards the metal in an angle exactly equal to that which it makes upon its

return after reflection; and there will probably be considerable irregularities in the interval of retardation, according to the mode of performing the experiment; although in general the irregular dispersion or diffraction from the glass is too weak to afford colours easily observable, when the position of the plate differs considerably from that in which the light is regularly reflected. If a portion of polarised light is incapable of interfering with another portion polarised in a transverse direction, these rings ought to disappear when the angle of incidence on the plate of glass is about 55° , since in this case the light reflected by it is completely polarised in the plane of incidence: and this disappearance seems actually to have been observed in some of Mr Arago's experiments, though in others, where the metallic surface was less highly polished, the polarisation of the dispersed light may have been less complete, and the rings may still have been visible at this angle. (*Mémoires d'Arcueil*, Vol. III. p. 354, 359.)

SECTION VI.—Of the Colours of Double Plates.

When light is transmitted in succession through two plates, differing but little in thickness, they exhibit an appearance of colour similar to that which would be produced by a single plate equal in thickness to their difference; and this appearance is wholly independent of the distance of the plates from each other. It was first noticed by Mr Nicholson, in the glasses employed for the sights of sextants, and is attributed by Dr Young to "the rays twice reflected within the first glass only, interfering with the rays twice reflected in the second only:" in some circumstances, however, the light returning from the second glass to the first, and again reflected by it, may cooperate in the effect; the interval of retardation being the same in both cases. Mr Knox has more lately described some very striking appearances of colours, obtained in this way, by the combination of two pairs of lenses, each exhibiting their appropriate rings when viewed separately, and affording together a third series of rings of larger dimensions, when the two former are unequal in magnitude, and of straight bands when they are equal. It is in fact easily demonstrable, that in order that the thicknesses of the plates of air, contained between two unequal pairs of lenses, may be equal, the distances from the centres of contact must be in a constant proportion; and it is well known that all the points, from which the lines drawn to two given points are in a constant proportion, will be found in the circumference of a circle, the diameter of which is a third proportional to the difference and sum of the segments of the given distance of the points: so that the colours, depending on this difference, instead of beginning as usual from a white central spot, will begin from a white ring, and will be arranged in concentric rings on each side of it, precisely in the same order as when they form concentric rings round an actual point of contact: and when the curvatures of the two pairs of lenses are equal, the diameter of the circle becoming infinite, it will obviously be converted into a right line.

Dr Brewster has observed a series of similar phenomena, produced by two plates, of equal thickness.

Chromatics. but forming a small angle with each other, so as to be differently inclined to the light passing through them. The effect of the inclination being to reduce the virtual thickness of the plate in the ratio of the cosine, and the difference of the cosines of equi-different arcs being simply as the sine of their half sum, it is evident that the colours must correspond to a thickness which varies nearly as the sine of the angle of incidence, considered with regard to a plane bisecting the angle formed by the plates: and this result agrees correctly with Dr Brewster's experiments.

SECTION VII.—Of the Colours of Supernumerary Rainbows and Glories.

Within the common primary rainbow, and without the secondary, we sometimes observe a partial repetition of colours, more or less distinctly marked, and extending occasionally to several alternations; the repetitions occupying somewhat narrower spaces as they are more remote from the ordinary bows. These appearances seem to have been first described by Mariotte; they have been since noticed by Langwith, Daval, and Dièquemarc; and the term supernumerary rainbows has been very properly applied to them. The coloured circles, called glories, may generally be seen surrounding the shadows of our heads, when we have an opportunity of standing on a high hill, and observing them in a cloud below us: they are also sometimes accompanied by a large white circle, which, in an observation of Ulloa, was 67° in diameter: and such a circle may frequently be distinguished when the sun shines on a mass of vapour rising from a warm bath, of nearly the same dimensions, or sometimes a little smaller. The whole of these phenomena may be explained from the interference of some of the portions of light regularly reflected within the minute drops of water, with other portions, incident at a different angle, but, after an equal number of reflections, coinciding ultimately with them in direction; supposing only the clouds in question to afford a number of these drops varying but little from each other in diameter. We find by the well known mode of calculating the greatest deviation, that each order of reflections exhibits a zone from 30° to 10° in breadth, through which a double light is diffused by each drop; and besides this, when there have been more than three reflections, the portions belonging to the opposite sides cross each other in one or more points, and surround the drop; or rather the observer, if we consider the effect of the refraction of a multitude of drops situated in all directions. Supposing the index of refraction for the extreme rays 1.336, and its logarithm .1258000, the results will be these.

After reflection	Extreme Deviation.	Final Deviation.	We may observe a more distinct idea of these duplicatures, if we represent them in a diagram, showing the angular extent of the diffusion of light derived from each order of reflections, and dis-
2	$41^\circ 40'$	$13^\circ 52'$	
3	$51 \quad 41$	$69 \quad 12$	
4	$40 \quad 39$	$27 \quad 44$	
5	$45 \quad 2$	$55 \quad 20$	
6	$50 \quad 0$	$41 \quad 36$	
	$34 \quad 14$	$41 \quad 28$	

tinguishing by different kinds of lines the portions belonging to the opposite halves of the drops: and it will be obvious from the inspection of this figure, that the appearances in question have only been observed within some of the duplicatures of the orders to which they belong, between the angles of extreme and of final deviation. The tertiary and quaternary bows (III. IV.) are evidently too near the luminary to be visible: the quinary (V.) ought to be seen in the space between the primary and secondary, but it is probably much too faint to be visible under any circumstances. The duplicature belonging to the primary rainbow exhibits two portions, for which we may calculate the interval of retardation in parts of the radius of the drop, supposing the velocity to be that which is appropriate to the air, by taking twice the difference of the cosines of incidence on the drop, and multiplying twice that of the cosine of refraction by the index 1.336; the difference of these differences giving the interval, for the two portions, of which the direction has been found to coincide by a previous calculation.

Distance from the Edge.	Angle of Reflection.	Difference of the Paths.	Hence it may be inferred, that, supposing the extreme red to reappear at the distance of 2° from the primitive external termination of the rainbow, the radius of the drop must be .0000266 .004
0°	$40^\circ 2'$.0000	
1	$42 \quad 59$.0014	
2	$44 \quad 2$.0040	
3	$44 \quad 45$.0074	
4	$38 \quad 3$		
	$45 \quad 20$.0118	
	$31 \quad 45$		
5	$45 \quad 46$.0160	
	$80 \quad 34$		
6	$46 \quad 9$.0210	
	$29 \quad 26$		
8	$46 \quad 45$.0327	
	$27 \quad 20$		
10	$47 \quad 12$.0461	
	$25 \quad 24$		
12	$47 \quad 32$.0612	
	$23 \quad 28$		

must be .0000266 .004
 .00665, or $\frac{1}{150}$ of an inch; the fourth alternation of the red being at the distance of 5° , where the interval is .016. The magnitude of the interval, at an equal distance from the edge, varies but lit-

Chromatics. the with the refractive density : thus, for violet light, the index of refraction being probably about 1.346, and its logarithm .1290000, the greatest deviation will be found $40^{\circ} 14'$; and for a deviation 2° less, the angles of refraction must be $43^{\circ} 30'$ and $33^{\circ} 47'$, and the interval will be little different from .00400.

The supernumerary bands of the secondary bow, formed by the same drops, will be a little broader than these, since it appears, from a similar calculation, that the rays interfering with each other, at the distance of a degree from the edge, will exhibit an interval of .0011 of the radius only, instead of .0014.

The supernumerary colours of the third and fourth bows will be equally imperceptible with the bows themselves : but the portions of light, four times reflected, will cross each other in the point opposite to the sun, where their coincidence will be perfect, and at other neighbouring points will afford an interval nearly proportional to the distance from that point. We shall find that the intervals for different deviations, supposed to be measured in air, are these.

Deviation.	Angle of Reflection.	Interval in parts of the Radius.	first bright or greenish ring to appear at the distance of 5° from the observer's head, the radius of the drops must be about
180°	24° 49'	.000	$\frac{.0000225}{.096} =$
185	25 31	.096	$\frac{.000234}{.1370} =$
175	24 7		
190	26 14	.195	.000234, or $\frac{1}{4370}$ of an inch.
170	23 25		

It might be questioned, whether the light, five times reflected, could retain sufficient force to produce any sensible effects by these interferences, but since it exhibits no appearance of colour between the primary and secondary rainbows, it must necessarily be extremely faint. The interval which it affords, by the comparison of its two portions, agrees sufficiently well with that which is derived from four reflections, to contribute in some measure to the production of an alternation of light and shade ; but the separate colours would be rather weakened than strengthened by the mixture : thus, at the deviation of 5° , the interval is found to become .076 instead of .096 ; and at 10° , .155 instead of .195 : and this difference is too considerable to allow us to expect any material increase of brilliancy from the addition of the fifth reflection, however great its intensity might be.

Supposing now a cloud to consist of spherules of which the radius is .000234, we may inquire at what distance from the outer edge of the primary rainbow the first additional red of the supernumerary colours ought to be found : the interval being in parts of the

radius $\frac{.0000266}{.000234} = .116$: and we may infer from

the table, by taking the successive differences, that this distance will be about 18° ; so that the semidiameter of this red ring will be $42 - 18 = 24^{\circ}$: and the position of the primitive band of red, supposing to extend to one fourth of a complete interval only, will be where the difference is .029, or at $7\frac{1}{2}^{\circ}$;

but for the violet the quarter of the interval will be, Chromatics.

in parts of the radius, $\frac{.0000042}{.000234} = .0183$, which an-

swers to a distance from the edge of about $5\frac{1}{2}^{\circ}$: and this distance, measured from the edge of the violet, which is somewhat less than 2° within that of the red, will extend nearly to the same point as the red space : so that we shall have a circle, about 70° in diameter, at the circumference of which all the colours will be united, and which will consequently be white. This magnitude agrees tolerably well with the direct observations of the phenomenon : and if we wish to make the agreement more complete, we have only to suppose the drops a little smaller, and the coloured glories, which they are capable of affording, a little larger. It has already been remarked, that the nonappearance of the ordinary rainbow, in this case, must be referred to the operation of something like diffraction ; although it is obvious that its form, under such circumstances, would necessarily be somewhat modified by the diffusion of the colours through a greater space than that which they ordinarily occupy.

SECTION VIII.—Of the Colours of Striated Substances.

It was observed by Boyle, that small scratches of any kind, on the surfaces of polished substances, exhibited, when viewed in the sunshine, a variety of changeable colours ; and the observation may easily be repeated with any piece of metal, not too highly polished, and placed in a strong but limited light. Dr Young ascertained by experiment, that the colours afforded by some regular lines, drawn on glass, always corresponded to an interval, varying as the sine of the angle of deviation from the position, in which an image of the luminous object was exhibited by the regular reflection of the surface ; and it is easily shown, that if we suppose two portions of light to be reflected from the opposite edges of the furrow, the difference of their paths must vary in that proportion. Dr Young had conjectured that the colours of the integuments of some of the coleopterous insects might be derived from furrows of this nature ; but the conjecture has not been verified by observation. Dr Brewster has, however, very unexpectedly discovered, that some similar inequalities are the cause of the colours exhibited by mother of pearl ; and he has confirmed the observation by showing, that impressions of the surface of this substance, taken in black wax, in a hard cement, or in fusible metal, will often exhibit a similar appearance. Where the form of the surface of the mother of pearl is the most regular, it reflects, in an oblique light, a white image of a luminous object, like that which any other polished substance affords ; but on one side of this image only, and at some little distance from it, we may observe the first order of recurrent colours, beginning from violet, and occasioned in all probability by the reflections from one side only of an infinite number of parallel striae, formed by the terminations of a minute lamellated

Chromatics. structure, nearly, but not perfectly perpendicular to the general surface; one side only of each of the little furrows being situated in such a direction as to reflect an image of the luminous object to the eye, and at such a distance that the whole may constitute a regular series of equal intervals. By transmitted light, this substance generally appears of a red or a green colour, changing more or less according to the obliquity, and apparently belonging to some of the higher orders of recurrent colours.

Dr Young has observed a series of these colours, produced by the parallel lines of some of Coventry's glass micrometers, drawn at the distance of $\frac{1}{300}$ of an inch from each other, in which the first bright space, or the confine between the green and the red, corresponded to the interval of $\frac{1}{3300}$ of an inch, or .0000232 (*Medical Literature*, p. 559); and this result agrees very accurately with the general theory, the interval for the yellow, derived from Newton's measurements, being .0000235; but in general these lines exhibit colours much more widely extended, each separate line consisting in reality of two or more scratches, at a minute distance from each other.

There is a remarkable peculiarity in the appearance both of these colours, and of those which are exhibited by substances naturally striated, as by mother of pearl, agate, and some other semitransparent stones; they lose the mixed character of periodical colours, and resemble much more the ordinary prismatic spectrum, with intervals completely dark interposed. This circumstance may be satisfactorily deduced from the general law, if we consider, that each interference depends not only on two portions separated by a simple interval, but also on a number of other neighbouring portions, separated by other intervals which are its multiples; so that unless the difference of the two paths agrees very exactly with the interval appropriate to each ray, the excess or defect being multiplied in the repetitions, the colour will disappear; consequently each of the stripes, which in other cases divide the space, in which they appear, almost equally between light and darkness, when homogeneous light is employed, becomes here a narrow line; and their succession affords a spectrum exhibiting very little mixture of the neighbouring colours with each other, and nearly resembling that which is afforded by the simple dispersion of the prism; except that, as in all other phenomena of periodical colours, the blue and violet portions are much more contracted than in the common spectrum.

SECTION IX.—Of the Colours of Mirrors, and of thick Plates.

In all the species of periodical colours which have been described, the two portions of light concerned have both been regularly reflected from different surfaces. The methodical division of the subject now leads us to the consideration of the colours exhibited in light separately reflected from the same surface. These may be denominated in general the colours of mirrors; and they will include, as a variety, those which are called by Newton the colours of thick plates.

Chromatics. The general character of these colours is, that they are observed in light reflected by small particles, or irregularly dissipated by a single surface, first in the passage of the beam of light towards the mirror, and then in its return: the difference of the length of their paths affording, as usual, the interval of retardation. Thus in Dr Herschel's experiment of scattering a fine powder in a beam of light reflected perpendicularly by a concave mirror, and received on a screen in its return, it may easily be shown, that the colours will be precisely such as would be exhibited by light transmitted through a thin plate of air, every where half as thick as the plate limited by two spherical surfaces in contact; the centre of the one surface being the particle of powder, and that of the other its image formed by the mirror. For in the direction of the principal ray, which is perpendicular to the mirror, the paths of the light will be of equal length, whether the dissipation takes place before or after the reflection; and in other parts, the whole length of the path of the light passing from any focal point to its conjugate focus being the same, according to the definition of a conjugate focus in the Huygenian theory, from whatever point of the mirror it may be reflected, the light first dissipated will have advanced, after its reflection as far as the circumference of a circle, of which the conjugate focus is the centre, at the same instant that the portion coming directly from the powder, after a previous reflection, will reach the circumference of the circle of which the particle of powder is the centre; so that the distance between these two circles must be the difference of the paths of the two portions, and the colours the same as would be exhibited by a plate of air of half the thickness, since such a plate is twice traversed by the retarded light.

A similar appearance of colours had been obtained, by earlier experimenters, from the interposition of a screen of gauze, or of a semitransparent substance, in the path of the beam falling on the mirror. But the colours of thick plates, observed by Newton, are modified by the nature of the transparent substance employed, and by the obliquity of the refracted light. The dissipation here takes place at the anterior surface of a concave mirror of glass, and the reflection at the posterior, which is coated with quicksilver: and if these two portions proceed, each with a slight divergence, from a perforation in a screen situated near the centre of curvature of the mirror, they will cooperate perfectly with each other in the circumference of a circle described on the screen, of which the diameter is the distance of the perforation from its image; since all the light passing, in any given section of the mirror, with the same obliquity through the glass as the beam itself passes in the principal section, must be collected into a focal point situated in some part of this circle, and will arrive at this point at the same time whatever its situation in the section may have been: the obliquity of the incident light being the same in every part of the section, because the point of divergence is at the same distance from the mirror as the centre of curvature. For the other parts of the dissipated light, passing with different obliquities, the interval will be determined by the difference between the lengths of

Chromatics. the paths of the two portions of light arriving at the given point, the one by regular refraction, after being first dissipated and then reflected: the other by dissipation, after being first regularly refracted and reflected. And this interval agrees precisely with the law which Newton has deduced from his experiments: but the analogy, which he infers from it, between these colours and those of thin plates, is in fact very far from amounting to identity; since, if they belonged to the ordinary colours of thin plates, there is no reason why the series should begin anew from a certain arbitrary thickness, differing in every different experiment, which affords a white of the first order.

SECTION X.—Of the Colours of deflected Light.

We are next to examine the case of light only once reflected, and interfering with a portion of the same beam which has pursued its course without interruption: a case which would scarcely have required a separate consideration, but from the difficulty of including it in a general definition with any others; although it is comprehended in the Newtonian description of the colours of inflected light: but since the light is in this case turned away from the substance near which it passes, it may more properly be termed deflected, especially as the greater number of the appearances, mentioned by Newton, as depending on inflection, belong more properly to diffraction, and the term inflection might consequently be misunderstood as relating to them.

When a beam of light is received in a dark room, and suffered to fall upon the edges of two extremely sharp knives or razors, meeting each other in a very acute angle, the shadows of the knives, received on a screen at some distance, will be found to be bordered by several fringes of colours; and the angle will be bisected by a dark line. The distances from the shadows, at which these fringes appear, agree in general with the supposition of their depending on the interference of the light, reflected from the edges of the respective knives, with the uninterrupted light of the beam passing between them: but the coincidence of these portions ought to be perfect, in the immediate neighbourhood of the point in which the shadows meet, and the two last bright fringes ought to unite there in an angle of light. This, however, does not happen on account of the modification of the general law (C), which makes it necessary to allow half an interval for the effect of a very oblique reflection: and for the same reason, the space immediately next to the shadow is always dark instead of being light. If the knives are at all blunt, the reflection from one to the other, where they meet, causes the bisecting dark line to disappear; but this source of error may be avoided by causing one of them to advance a little before the plane of the other.

Mr Fresnel has repeated these experiments with all possible care, and has ascertained that the points, in which the fringes of any one colour are found, at certain distances from their origin, belong always to a hyperbola, as they ought to do according to the calculation founded on the general law of interference; a fact which had before been inferred from other

measurements, but which had not been so distinctly proved by direct experiments. Newton himself, indeed, was so far from believing that these fringes are rectilinear, as Mr Fresnel supposes, that he expressly mentions their curvature, and infers from it that they are not derived from "the same light" in all their parts; imagining, perhaps, that each fringe was of the nature of a caustic line, formed by reflection or refraction, in which the light is every where more condensed than in the collateral spaces, but which is by no means necessarily straight. Mr Fresnel has also shown, that all the fringes are found exactly at such distances from the true shadow, as would be inferred from the supposition of the loss of half an interval by reflection; while some of the experiments of Newton appeared to indicate a deviation from this law. It has been asserted, that fringes of the same kind have been observed at the edges of a detached beam of light, reflected into a dark space by a narrow plane and polished surface; and in this case it would be difficult to point out in what manner the supposed oblique reflection could be produced, or how a diffraction of any kind could cause the light to be redoubled back upon itself: but the experiment does not appear to have been hitherto performed with sufficient attention to all possible sources of error.

SECTION XI.—Of the Colours of diffracted Light; including those of Fibres, and of Coroneæ.

The light reflected from each of the knife edges, in experiments like those of Newton, not only produces colours by its interference with the light proceeding uninterruptedly between them, but also with another portion, diverging from the edge of the opposite knife, and spreading into its shadow. This tendency of light to diffuse itself was first described by Grimaldi, under the appropriate name diffraction: but many of the phenomena, in which it is concerned, having been attributed by Newton to other causes, he appears almost to have overlooked its existence.

The general law of interference is very directly applicable to all phenomena of this kind: the fringes exhibited are broader in the same proportion as the distance between the edges is narrower; and they always depend on the difference of the distance from the edges as the interval of retardation. It is however necessary to suppose the same modification to take place in diffraction as in oblique reflection, half an interval being lost in both cases; since the light which deviates the least from a rectilinear direction, and which is derived from the near approach of the two paths to equality, is always white. But it is remarkable, that when the obliquity becomes a very little greater, the diffracted light seems to change its character in this respect; for the colours occupy the same spaces as would have belonged to them, if they had begun from a dark centre, one of the portions only having lost a half interval in comparison with the other: and of this circumstance no explanation has yet been attempted.

The diffraction producing these fringes may easily be detected within the eye itself, by holding any ob-

Chromatics. ject near it, in such a position as to intercept nearly all the light of a candle except a narrow line at the edge; this line will then appear to be accompanied by other lines parallel to it, separated from it by a dark space, and becoming wider when the object is brought nearer to the eye. These fringes must be referred to the light diffracted on one side round the object, so as to be spread on the unenlightened part of the retina, and reflected on the other from the margin of the pupil: for if we employ an object narrower than the pupil, so as to observe them on both sides of it, their magnitude will be altered by any change in the aperture of the pupil, occasioned by admitting light to the opposite eye, or otherwise. In such cases as this, where one of the points of divergence is much nearer to the point of interference than the distance from the primitive direction; and the first fringes are much broader than those which succeed them; the mode of their formation approaching to that of the fringes seen in deflected light, commonly called the exterior fringes of the shadow; while the interior fringes belong more immediately to the present subject, that of the colours of diffracted light.

When the distance of the points of divergence is more nearly equal, the one being collateral to the other, the breadth of the successive fringes is also more uniform. Such is the appearance of the colours exhibited by a number of equal fibres held between the eye and a distant luminous object; their origin being identical with those of the fringes produced in the shadows of the knives; except that the diffracted rays come from the remoter side of the fibres, and follow the reflected rays, instead of preceding them. These colours may easily be observed by looking at a candle through a lock of fine wool, and still more distinctly by substituting for the wool some of the seeds of the lycopodium, strewed on a piece of glass; and they become very large if we employ a few of the particles of the blood, or the dust of the lycoperdon, or puff ball. Dr Young has made this appearance the foundation of a mode of measuring the fineness of wool, which he has recommended for agricultural purposes, though it seems hitherto to have been found much too delicate to be employed by "the hard hands of peasants," with any advantage. The instrument, which he has invented for this examination, is called the eriometer, and its scale is calculated to express, in semidiameters of a circle, formed round a central aperture in a card, or a plate of brass, and marked by minute perforations, the distance at which the lock of wool must be held, in order that the first bright ring of colours, or the limit of the green and the red surrounding it, may coincide with the circle of points; and the actual measure, expressed by a unit of this scale, is found to agree very nearly with the thirty thousandth of an inch. Thus the particles of water, which have been found capable of exhibiting a glory 5° from the shadow of the observer, being about $\frac{1}{35}$ of an inch in diameter, they would correspond to number 14 of this scale; and the cotangent of the angle subtended by the semidiameter of the bright circle being 14, the angle itself will be about

Chromatics. 4° ; consequently, if we looked at the sun through such a cloud, he would appear to be surrounded by a bright circle of colours, 8° in diameter, green within, and red without, and attended by other colours, more or less distinctly marked, according to the degree of uniformity of the magnitude of the drops. These circles are called coronæ: their dimensions vary considerably; but they have seldom been observed quite so large as these drops would make them; and more commonly they seem to depend on drops about a thousandth of an inch in diameter; although it is not easy to ascertain the precise parts of the rings, from which the measures have been taken by different observers.

In the shadow of a larger substance, formed in a beam of light admitted into a dark room, these colours are still perceptible, beginning from a white line in the middle: but here both the portions, on which they depend, are diffracted into the shadow; and beyond its limits, they are lost in the stronger light that passes on each side of it. Their appearance is somewhat modified, when the shadow is formed by a body terminating in an angle; for the breadth of the fringes being inversely as the breadth of the object which forms them, it is obvious that this breadth must increase towards the point of the shadow, like the distance of the fringes formed in the shadows of Newton's knives: and the fringes seen within the angle must necessarily assume the character of hyperbolas: nor will this form be materially altered, when the angle becomes a right one, as in the crested fringes, noticed by Grimaldi; although the steps of the calculation, for determining their magnitude, are in this case a little more complicated.

We find, in an elegant experiment of Mr Biot, on the fringes produced by diffraction, a singular confirmation of the truth of the theory, which derives these colours from the difference of the times occupied in the passage of the different portions of light to the point of interference: although this celebrated author does not seem to have been aware of the nature of the inference, which may so naturally be drawn from it. He found that the densities of the substances, from the margin of which the diffracted light originated, had no influence whatever on the appearances produced by them: but when they were formed in the light diffracted from substances placed at one end of a long tube, and observed on a piece of glass fixed at the other end, they became contracted, upon filling the tube with water, in the proportion of 4 to 3; as was to be expected from the diminished velocity which must be attributed, according to the modification of the general law (B), to the passage of the light through a denser medium.

SECTION XII.—Of the Colours of mixed Plates.

The colours of mixed plates depend partly on diffraction, and partly either on reflection or on direct transmission: but their essential character consists in the different nature of the two mediums, through which the light passes after its separation.

When a minute quantity of moisture is interposed

Chromatics. between two lenses, it readily divides itself into a great number of smaller portions, scarcely distinguishable by the eye: and the light transmitted through the lenses exhibits rings of colours much larger than those which are ordinarily observed, and depending on the interval afforded by the difference of the velocities in the different mediums, according to the inverse proportion of the refractive densities. If they are viewed in a direct and unconfined light, the rings belong to the series commonly seen by transmission, beginning from a light central spot: both portions passing in this case simply through the separate mediums, and arriving at the eye after some slight diffraction only, which affects both of them in an equal degree: but if a distant dark object is situated immediately behind the lenses, and they are illuminated by a light incident a little obliquely, their character is changed, and they resemble the colours commonly seen by reflection, one of the portions of light being necessarily reflected, as in the case of the colours of deflected light: so that, when the dark object is situated behind one half of the glasses only, we observe the halves of two sets of rings, of opposite characters, exhibiting everywhere tints complementary to each other. The diameters of the rings vary according to the refractive density of the liquid employed, diminishing as that density increases, and becoming much larger when two liquids, incapable of mixing with each other, and differing but little in refractive density, as oil and water, are employed instead of air and a single liquid.

The magnitude of the interval may also depend on that of a minute transparent solid substance, immersed in a liquid, instead of being limited by the distance of the two lenses: thus the dust of theycoperdon, mixed with water, gives it a purplish hue, when seen by indirect, and a greenish by direct light: and when salt is added to the water, or oil is substituted for it, the difference of the velocities being lessened, the colours exhibited rise in the series, as if the plate were made thinner.

Mr Arago has very ingeniously applied the principle of the production of these colours, to the construction of an instrument, for measuring the refractive densities of different elastic fluids, and of air in different states of humidity; the fluids being contained in two contiguous tubes of a given length, through which the two portions of light are made to pass, previously to their reunion, and to the formation of the bands of colours; and it may easily be conceived, that the delicacy of such a test must be great enough for every determination that can be required, either for the correction of astronomical observations, or for the illustration of the optical properties of chemical compounds.

SECTION I. —Of the Laws of the Polarisation of Light.

Colours first observed by Mr Arago, in refracting crystals, and since more particularly analysed by Mr Biot, afford by far the most striking and interesting examples of the colours of mixed plates. In order to understand the laws of

Chromatics. these phenomena, it is necessary to be previously acquainted with the affections of polarised light, which were first accurately investigated by Malus, and with the theory of extraordinary refraction, derived by Huygens, with equal elegance and precision, from his peculiar hypothesis respecting the nature of the transmission of light.

1. Mr Malus discovered, that at a certain angle of incidence, the light partially reflected, by a transparent substance, receives a peculiar modification with respect to the plane of reflection, which is called *polarisation in that plane*.

2. Dr Brewster observed, that the *angle of complete polarisation* is such, that the mean direction of the transmitted light is perpendicular to that of the reflected portion; the tangent of the angle of incidence being equal to the index of the refractive density of the medium.

3. A ray of polarised light is again subdivided, in the usual proportion, by a second refraction in the plane of polarisation: but when it is refracted in a *plane perpendicular* to the plane of polarisation, by a surface properly inclined, *there is no partial reflection*: and in intermediate positions, the intensity of the reflection is nearly as the *square of the cosine* of the angular distance of the two planes.

4. A portion of the *transmitted light* is polarised in a *direction perpendicular* to that of the plane of refraction, so that none of this portion is reflected by a second surface parallel to the first; and when there are several parallel surfaces in succession, the whole of the transmitted light becomes at last so polarised, that none of it is partially reflected.

5. The same transverse polarisation will happen, in a *greater number* of transmissions, when the *angle differs* from that of complete polarisation: and in the same manner a second partial reflection, by a surface parallel to the first, will produce a more complete polarisation, when the first is imperfect.

6. A perfect polarisation in any new plane, by a partial reflection at the appropriate angle, completely *supersedes* the former polarisation: but a reflection or refraction void of any polarising effect, which may be called a *neutral reflection* or refraction, changes the direction of the plane of polarisation, according to Mr Biot's experiments, into that of the image of the former plane, supposed to be formed by the action of the given surface.

7. The light *ordinarily refracted* by a doubling crystal in the plane of the principal section of the crystal, passing through its axis, is *polarised in that direction*: the light *extraordinarily refracted* in the *transverse direction*.

8. Light *previously polarised* is transmitted by the ordinary refraction when its plane of polarisation coincides with the principal section, and by the extraordinary when it is perpendicular to it. In intermediate directions, the quantity of light transmitted by each refraction is, according to Malus, as the square of the cosine and sine of the angle formed by the planes, passing through the paths of the ray, and a line parallel to the axis in each crystal, supposing the species of refraction to be exchanged.

9. The rays of light ordinarily transmitted by doubling crystals appear in general to retain their

Chromatics. previous polarisation, like rays transmitted through simple substances; but the extraordinary refraction polarises them, according to Biot, like a neutral reflection at a surface coinciding with the principal section; the new plane of polarisation taking the place of the image of the former.

10. Reflections at *metallic surfaces* are generally neutral with respect to polarisation: but in oblique planes they seem, according to some experiments of Malus, to mix or depolarise the light subjected to them.

SECTION XIV.—Of the Laws of extraordinary Refraction.

The extraordinary refraction of regular doubling crystals may be correctly determined in all circumstances, by means of the Huygenian supposition of an undulation diverging in the form of a spheroid, from every point of the medium, the velocity in any given direction being always proportional to the corresponding diameter, so that the successive spheroidal surfaces remain always similar to each other. The relations of the angles of incidence and refraction may be calculated by finding the point, in which any of the spheroids, supposed to represent the forms of the elementary undulations, at a given instant, is touched by a plane passing through that point of the surface, at which the original beam of light would have arrived, at the same instant, through the external medium; it may also be deduced, somewhat more simply, from the determination of the velocity, with which an expanding spheroidal undulation must extend itself on any given surface; a velocity which immediately gives us the direction of the ray in the surrounding medium; and the relation thus obtained will also obviously hold good with respect to a ray returning in the opposite direction. (*Quarterly Review*, No. 21.)

In common refractions, if we compare the space described by an undulation or any given surface with the radius, the velocities appropriate to the different mediums will be represented by the sines of the respective angles. But the velocity, with which a spheroidal undulation advances on any surface, is evidently determined by the increment, or the fluxion, of the perpendicular to the circumference of the section of the spheroid, formed by that surface; and calling this perpendicular y , the velocity may be considered as proportional to its increment y' : but the velocity in the surrounding medium is to that, with which the axis x increases, as r to 1, r being the index of the ordinary refractive density of the crystal, compared with that of the surrounding medium, since the velocity in the direction of the axis is the same as that which belongs to the ordinary refractive density; consequently, the increment of the path of the undulation in the surrounding medium will be expressed by rx' , and s , the sine of refraction or incidence without the crystal will be to the radius as rx' to y' , and will be expressed by $\frac{r'}{y'}$, or by $r \frac{dx}{dy}$, the evanescent increments of any quantities being always in the ratio of their fluxions:

Chromatics. and the plane of refraction or incidence, without the crystal, will always be perpendicular to the tangent of the section formed by the refracting surface. The determination of the relation of the angles is therefore reduced to the calculation of the value of y and of its fluxion.

Supposing then the ratio of the greatest and least refractive densities of the crystal, or of the equato-

rial diameter of the spheroid $2AB$ to the axis $2AC$ to be that of n to 1, n being greater than unity, and the tangent of the angle ADE , formed by the axis

with the refracting surface DE , being called p ; the magnitude of the semidiameter AF , parallel to the surface, may be found by comparing the secants of the angles FAG , HAG , subtended at the centre by the corresponding ordinates of the el-

lipsis and the inscribed circle: for their tangents,

FG , HG , being represented by p and $\frac{p}{n}$, the secants

will be $\sqrt{1 + p^2}$, and $\sqrt{1 + \frac{pp}{nn}}$; and the se-

midiameter of the circle, AH , being x , that of the

ellipsis, AF , will be $n \sqrt{\frac{1 + pp}{nn + pp}}$ x . But the tangent

of the angle GIF , made by the tangent of the ellipsis with the axis, is to that of the angle made by the corresponding tangent of the circle, GIH or GHA ,

that is, $\frac{n}{p}$, as n to 1; consequently, $\frac{nn}{p}$ will be the tan-

gent of the angle made with the axis by the elliptic tangent, IF , or by the conjugate diameter AK ; and

if we substitute $\frac{nn}{p}$ for p , we shall find the length of

this diameter $AK = \sqrt{\frac{n^4 + p^2}{nn + pp}}$ x , which is to that of

the former AF in the ratio of $\frac{\sqrt{n^4 + p^2}}{n \sqrt{1 + pp}}$ to 1.

Chromatics. Hence, for the lesser semiaxis of the section formed by the given surface, EL, calling AL the distance of its centre from that of the spheroid, z , we have the mean proportional between the segments of the diameter $\sqrt{([AK+AL] \cdot [AK-AL])} = \sqrt{(AKq -$

$$ALq) = \sqrt{\left(\frac{n^4 + p^2}{nn + pp} x^2 z^2\right)}, \text{ which must be reduced}$$

in the ratio of the conjugate diameters AK and AF,

$$\text{so that it becomes } n \sqrt{\left(\frac{1+pp}{nn+pp} x^2 - \frac{1+pp}{n^4+p^2} z^2\right)}$$

= EL. But from the known similarity of the parallel sections of a spheroid, the axes will be to each

other as the semidiameter AF = $n \sqrt{\frac{1+pp}{nn+pp}} x$ is to

nx the equatorial semidiameter, a ratio which may be

called that of 1 to m , m being = $\sqrt{\frac{nn+pp}{1+pp}}$; so that

$$\text{the lesser axis EL being} = n \sqrt{\left(\frac{xx}{mm} - \frac{1+pp}{n^4+p^2} z^2\right)},$$

$$\text{the greater LP will be } n \sqrt{\left(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2\right)}.$$

Now, if q be the cotangent of the angle MNE, formed by the plane of the ray's motion, in the external medium, with the lesser axis of the section, or the tangent of the angle ELO formed by the conjugate semidiameter LO with the same axis, this semidiameter may be found by substituting q for p , m for n , and the value of the semiaxis of the section for x , in the expression for AF, the semidiameter parallel to the refracting surface, and it becomes

$$m \sqrt{\frac{1+qq}{mm+qq}} EL = n \sqrt{\frac{1+qq}{mm+qq}} \left(\frac{xx}{mm} - \frac{1+pp}{n^4+p^2} z^2\right)$$

= LO. Hence, since all parallelograms described about an ellipsis are equal, dividing the product of the semiaxes EL.LP by this semidiameter, we shall

$$\text{have the required perpendicular } y = MQ = \frac{EL.LP}{LO} =$$

$$\frac{LP}{n} \sqrt{\frac{mm+qq}{1+qq}} = \frac{n}{m} \sqrt{\frac{mm+qq}{1+qq}} \sqrt{\left(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2\right)}.$$

Now, in order to find the fluxion of this quantity, increasing as the spheroid increases, while the place of the centre of radiation remains unaltered, we must make z constant while x varies, and we shall have

$$dy = \frac{n}{m} \sqrt{\frac{mm+qq}{1+qq}} x dx : \sqrt{\left(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2\right)},$$

which must be equal to $\frac{r dx}{s}$; consequently,

$$\sqrt{\left(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2\right)} = \frac{ns}{mr} \sqrt{\frac{mm+qq}{1+qq}} x; \text{ and}$$

axis of the section, EL, which was

$$\sqrt{\left(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2\right)}, \text{ becomes } \frac{ns}{mmr}$$

$$\sqrt{\frac{1+qq}{1+qq}} x, \text{ whence the semidiameter LM at the}$$

point of incidence, which may be called w , and which is analogous to the conjugate diameter AK in the

$$\text{former section, will be } \sqrt{\frac{m^4 + q^2}{mm+qq}} \cdot \frac{nn}{mmr} \sqrt{\frac{mm+qq}{1+qq}} x$$

$$= \frac{nn}{mmr} \sqrt{\frac{m^4 + q^2}{1+qq}} x. \text{ Hence it is obvious, that this}$$

semidiameter, in any one plane of incidence, will be in a constant proportion to the sines, as Huygens himself demonstrated; so that, supposing x to be constant, and z to vary, the semidiameter w may be considered as an ordinate in the elliptic section passing through the point of incidence M and the diameter AK conjugate to the refracting surface, which is also the path of a ray falling perpendicularly on that surface from without: and the tangent of the angle ELM formed by this semidiameter with the

lesser axis of the given section, will be $\frac{mm}{q}$, which

determines the intersection of this oblique plane with the refracting surface.

But in order to find the angle made with the refracting surface in a plane perpendicular to it, we must compute LR, the distance of the centre of the refracting section from the point nearest to the centre of the spheroid: and the tangents of the inclina-

tions of the diameters to the axis being p and $\frac{nn}{p}$,

that of their mutual inclination will be $\frac{pn+pp}{p(1-nm)}$, since

$$\tan(a+b) = \frac{\tan a + \tan b}{1 - \tan a \tan b}; \text{ and the sine of the same}$$

angle being expressed by $\frac{\tan a + \tan b}{\sec a \sec b}$, it becomes

$$\text{here } \frac{nn+pp}{\sqrt{(1+p^2)} \sqrt{(n^4+p^2)}} = \sin FAK = \sin$$

$$ALR, \text{ which we may call } \tau, \text{ and the cosine } \frac{1 - \tan a \tan b}{\sec a \sec b}$$

$$= \frac{p(1-nm)}{\sqrt{(1+p^2)} \sqrt{(n^4+p^2)}} = t: \text{ and the required}$$

distance LR will be tz , and the distance of the centre of the spheroid from the refracting surface AR = τz . But MS, the perpendicular falling from the point of incidence, on the lesser axis of the section formed by the surface, being called u , the tangent of the angle MLS, subtended by it at the centre be-

ing $\frac{mm}{q}$, and its sine consequently $\sqrt{\frac{mm}{m^4+q^2}}$, we

$$\text{have } u = \sqrt{\frac{mmw}{m^4+q^2}} = \frac{n^2 x}{r \sqrt{(1+q)}}; \text{ and the dis-}$$

tance of this perpendicular from the centre, LS = v

$$= \frac{qw}{\sqrt{(m^4+q^2)}}; \text{ or if we call the sine of ordinary}$$

refraction $\frac{s}{r} = \xi$ and the sine of the inclination of

Chromatics. the plane of the ray's motion to the lesser axis,

$\sqrt{\frac{1}{(1+qq)}}$, k , and its cosine $\sqrt{\frac{q}{(1+qq)}}$ = h , we have

$u = n^2 p k x$, and $v = \frac{nn}{mm} p h x$. Hence the cotan-

gent of the angle ERM, formed by the line nearest to the ray in the section with the lesser axis, will be $\frac{v+tz}{u}$, if the value of s be con-

sidered as positive, when the ray is inclined on the refracting surface towards the axis of the crystal; for in this case the sign of t being negative, tz or LR will be subtracted from v or LS; and the reverse when s is negative. We have also for the hypotenuse RM, or the distance of the point of incidence from the point nearest to the centre of the spheroid, $\sqrt{(u^2 + [v+tz]^2)}$; consequently, the tangent of RAM, the angle of incidence or refraction within the crystal, will be $\frac{\sqrt{(u^2 + [v+tz]^2)}}{rz}$.

Now since it has been shown that $\sqrt{(x^2 - \frac{1+pp}{n^4+p^2} m^2 z^2)}$

= $\frac{ns}{mr} \sqrt{\frac{mm+qq}{1+qq} x}$, we have $z^2 = \frac{n^4+p^2}{mm(1+pp)}$

$(1 - \frac{nnss}{mmrr} \frac{mm+qq}{1+qq}) x^2$, and the cotangent of the inclination of the plane of refraction ERM, or

$\frac{v+tz}{u} = \frac{q}{mm} + \frac{tz}{u}$, becomes $\frac{q}{mm} + \frac{p(1-nn)}{m(1+pp)}$

$\sqrt{(1 - \frac{nn}{mm} [m^2 k^2 + h^2] s^2)} \cdot \frac{1}{n p k}$; and since $r^2 z^2 = (m^2 - n^2 s^2 [m^2 k^2 + h^2]) x^2$, the tangent of the angle of incidence or refraction within the crystal, which

is = $\sqrt{(\frac{uu}{rrzz} + \frac{vv}{rrzz} + \frac{2t}{r} \cdot \frac{v}{rz} + \frac{tt}{rr})}$ will be re-

presented by $\sqrt{(\frac{n^4 m^4 k^4 + n^4 h^4}{m^4 (m^2 - n^2 s^2 [m^2 k^2 + h^2])} s^2 +$

$\frac{2p(1-nn)nnkp}{(nn+pp)mm \sqrt{(m^2 - n^2 s^2 [m^2 k^2 + h^2])} +$

$\frac{[p(1-nn)]^2}{nn+pp})$. The value of the perpendicular

to the surface, AR or rz , is also of importance as immediately indicating, by its proportion to the axis x , the velocity of the undulation in the direction of the depth, which is therefore represented by $\sqrt{(m^2 - n^2 s^2 [m^2 k^2 + h^2])}$.

These expressions become somewhat simpler in many cases of common occurrence; thus, when the axis is parallel to the surface, $p = 0$, $m = n$, and $t = 0$, consequently, the tangent of refraction is

$\frac{q}{n} \sqrt{\frac{n^4 k^2 + h^2}{1(nnk + hh) s^2}}$, and the perpendicular velocity

$n \sqrt{(1 - [n^2 k^2 + h^2] s^2)}$. When the axis is perpendicular to the surface, p is infinite, $m = 1$, and

t is again = 0; and the tangent of the angle of re- Chromatics.

fraction is $\frac{nnq}{\sqrt{(1-nnq s^2)}}$, the perpendicular velocity being $\sqrt{(1-n^2 s^2)}$.

The retardation, produced by the passage of light through such a plate, being equal to the time occupied within the plate, diminished by a time proportional to the product of the tangent of the angle of refraction and the sine of the angle of incidence (see Section V.); it will be expressed, in the case of

a plate parallel to the axis, by $\frac{r}{n \sqrt{(1 - [nnk + hh] s^2)}}$

$s^2 \sqrt{\frac{n^4 k^2 + h^2}{1 - (nnk + hh) s^2}}$; and when the axis is per-

pendicular to the plate, by $\frac{r}{\sqrt{(1-nnq s^2)}} - \frac{snq}{\sqrt{(1-nnq s^2)}} =$

$\frac{r(1-nnq s^2)}{\sqrt{(1-nnq s^2)}} = r \sqrt{(1-nnq s^2)}$. The effect of any

small change in the form of the spheroid, on the retardation, may be found from the fluxions of these quantities, supposing n to vary; which, when properly reduced, making $n = 1$, will be $-r \frac{1-hh s^2}{\sqrt{(1-s^2)}} dn$,

and $-\frac{r s^2}{\sqrt{(1-s^2)}} dn$ respectively.

The values of r and n , for the principal substances, exhibiting the extraordinary refraction, which have been examined, are these:

Iceland crystal	$r = 1.657$	$n = 1.1140$	= 10:9
Arragonite . . .	1.693	1.1030	= 11:10
Ice	1.310	.9989	= 890:891
Quartz	1.558	.99444	= 179:180
Sulfate of lime	1.525	.99432	= 175:176
Sulfate of barita	1.635	.99295	= 142:143

In mica, according to Mr Biot, and in arragonite, according to Dr Brewster, there are two axes of crystallization; and the refraction of such substances may probably be represented, by supposing all the circular sections of a spheroid to become ellipses, so that the undulation may assume the shape of an almond.

SECTION XV.—Of the Colours of doubly refracting Substances.

In the case of doubly refracting substances, the first difficulty is, not to explain why the colours of double lights are sometimes produced, but why they are not more universally observable: since it might naturally be expected, as a consequence of the general law of interference, that two portions of the same beam, passing through a moderately thin plate of such a substance, in paths differing but little from each other, and coinciding again in direction, should, in all common cases, exhibit colours nearly similar to those of ordinary thin plates. It would, however, be difficult to conjecture, whether they ought to resemble the colours seen by transmission or by reflection; and the fact is, that both these series of co-

Chromatics. Colours are at once produced by the substances in question; but they are so mixed, that, without a particular arrangement, they always neutralise each other: and their formation appears to be also limited to certain peculiar conditions of polarisation, consistent with Mr Arago's observation, on the non-interference of two portions of light, polarised in transverse directions. Several of the cases, indeed, in which they are exhibited, remain still involved in some degree of obscurity; but it is easy to analyse the most important of the phenomena, and to reduce them, with great precision, to the general laws of periodical colours.

Mr Malus has demonstrated, by satisfactory experiments, that a beam of light, admitted into a doubly refracting crystal, is as much divided by partial reflection at the second surface, as by transmission at the first: the directions and the relative intensities of the two portions being precisely the same as those of the two portions of a ray similarly polarised, and returning to the second surface from without in an equal angle; so that, after a farther transmission at the first surface, all the portions become again parallel. When the ray is in the direction of the principal section, there is no separation, each of the pencils proceeding undivided, as they would do if they passed through a second crystal parallel to the first: and the separation becomes the most complete when the plane of incidence makes an angle of about 45° with the principal section; each of the portions o and e , into which the ray is divided upon its admission, affording then two reflections, oO and oE , eO and eE , of nearly equal intensity. The times occupied by the portions oO , eE , will differ most from each other, while oE and eO will describe their paths in equal times of intermediate length: but of these eO only will commonly interfere with oO , which has a similar polarisation in the plane of incidence, and oE with eE , both being polarised in a transverse direction; so that we have two series of colours, depending on an equal interval, except so far as they are distinguished by the inversion of one of the portions belonging to the extraordinary reflection, which renders the series of colours exhibited by them similar to that of the colours of common thin plates seen by reflection, while the ordinary reflection exhibits colours analogous to those of thin plates seen by transmission.

Mr Biot's usual mode of exhibiting these colours is to place a thin plate of sulfate of lime, or of any other crystal, on a black substance; to allow it to reflect the white light of the clouds at an angle of incidence of about 35° ; and to receive this light on a black glass, at an equal angle of incidence, in a plane transverse to the former, so that the plate may be viewed by reflection in the black glass. In this arrangement, the light reflected from the upper surface of the plate, being polarised in the first plane of reflection, is not reflected by the black glass, and consequently is rendered the colours less easily perceptible in mixture with them: the beams oO and eE , being by the ordinary reflection, are not polarised, and will be transmitted or reflected by the glass; but the beams oE and eE ,

being polarised in a transverse direction, will be partially reflected by it, and will exhibit a very brilliant colour, depending on their mutual interference. If, on the contrary, the black glass be turned round the ray, so that the second plane of incidence may coincide with the first, the ordinary rays only will be partially reflected by it, and the complementary colour will be exhibited by the union of the portions oO , eO ; but this colour will be less distinct, on account of its mixture with the white light reflected by the first surface.

Appearances of a similar nature may also be observed in the transmitted light; each of the refractions exhibiting the colour complementary to that which it affords by reflection, as happens in the ordinary colours of thin plates; and we must seek for the portions of light which afford them, in the successive partial reflections at the two surfaces of the plate, as in the case of the ordinary colours; the light simply transmitted by the separate refractions not exhibiting the ordinary effects of interference, for want of a similarity of polarisation. The obliquity of the incident light produces similar effects on both series.

Under some circumstances of the reflection of rays near the perpendicular, Mr Biot observes that the plate assumes the colour which is usually exhibited by a plate of twice the thickness viewed a little more obliquely: and in such cases it is probable that the polarisation of the beams oO and eE has been so modified as to afford a partial interference; and if this is not the true explanation, it will not be difficult to suppose the interval to be doubled in some other manner by a repeated reflection.

The effect of a plate of a double thickness is also produced by two equal and parallel plates, through which the light passes in succession, provided that their axes of crystallization be parallel, and that they be of such a thickness, as to exhibit in conjunction a colour more easily observable than those which they afford separately: a condition which is more generally applicable to the case in which the axes are transverse to each other, and one of the thicknesses is to be subtracted from the other; since in this situation the two portions of light must always interchange their refractions, and that which has moved the more slowly, in its passage through one of the plates, will move the more rapidly in the other. This result is very accurately confirmed by experiment, and certainly affords a very striking illustration of the truth of the law of interference.

When we wish to examine the effects of the different obliquities of the incident light, it is most convenient to employ a beam previously polarised, which renders the separation of the different portions by a subsequent reflection or refraction more easily practicable: and for these purposes we may either make use of plates of black glass, placed in proper situations, or polarising piles, consisting of a number of oblique thin plates, which produce the effect, on the light transmitted through them, with less diminution of its intensity than would take place in a single partial reflection. In some cases also, the light may be analysed by causing it to pass through

Chromatics. a piece of Iceland crystal; or through a thin plate of agate, which Dr Brewster has found to transmit only such light as is polarised in a particular plane.

The measurements of the thickness of plates of doubly refracting substances agree in general very accurately with the various tints exhibited by them in various situations with respect to the axis, and with various obliquities of the incident light, according to the theory of periodical colours: and the agreement is always sufficiently perfect to convince us of the dependence of the phenomena on the law of interference, even if it should happen to require some unknown modification in particular cases. In the first place, when the incidence is perpendicular, the thickness of the plates is precisely such as would be inferred from the theory, at least as nearly as the theory is founded on observations sufficiently accurate, although this thickness is often many hundred times as great as that of the thin plates, with which it is to be compared: thus the greatest disproportion of the ordinary and extraordinary refraction of rock crystal, according to Malus's experiments, is that of 159 to 160; so that the difference of the times, occupied by light in passing through this substance, is to the interval, in virtue of which a similar plate exhibits the common colours, as 1 to 320, and to the interval in a plate of crown glass as 1 to 318; while the experiments of Mr Biot make the observed proportion that of 1 to 360; the difference being no greater, than would arise from an error of less than a thousandth part of the whole, in the determination of one of the refractive densities.

The effect of the obliquity of the incident light, on the colours exhibited by plates of rock crystal, agrees also perfectly with the theory. The difference of the times required for the ordinary and extraordinary refractions, which is always comparatively small, will vary as the fluxion of the retardation, when the obliquity varies; and the sine of ordinary refraction being g , the interval will be expressed by

$$-r \frac{1-hhgg}{\sqrt{(1-gg)}} dn, \text{ when the axis is parallel to the}$$

surface of the plate, and by $-r \frac{gg}{\sqrt{(1-gg)}} dn$, when

it is perpendicular. Taking, for example, an experiment of Mr Biot, on a plate in which the axis was nearly perpendicular, the mean angle of refraction being $21^{\circ} 38.5'$, the tint was a reddish white of the seventh order, answering to the reflection from a plate of glass .0000496 of an inch thick, in the experiments of Newton, while the colour exhibited, in a perpendicular light, by a plate of the same crystal, in which the axis was parallel to the surface, would have been expressed by the thickness .000332. In these two cases, the values of the fluxion become $-rda$ and $-1.46337dn$; and reducing the interval .000382 in this proportion, we find .0000486 for the thickness of a plate of glass which ought to exhibit the tint corresponding to the oblique incidence; the difference from the experiment being only one millionth of an inch, which would scarcely make a sen-

sible alteration in the colour observed. When the thickness of such a plate is more considerable, or when the eccentricity of the extraordinary refraction is greater, the colours differ, with the incidence, in different parts of the plate; and they are generally disposed in rings concentric with the axis. These rings have been particularly described by Dr Brewster, as observed in the topaz: they are always interrupted by a dark cross, occasioned by the want of light, properly polarised to afford them, in the two transverse directions.

Mr Biot has made a great number of experiments on the colours of the plates of sulfate of lime, in the form denominated Muscovy talc: they exhibit a general agreement with the results of the calculation, particularly with respect to the constancy of the tint, in all moderate obliquities, when the inclination of the axis to the plane of incidence is 45° ; but in other cases the agreement is somewhat less perfect, and the difference is too great to be attributed altogether to accident. The most probable reason for this irregularity, under circumstances so nearly similar to those which accord with the theory in the case of rock crystal, is the want of a perfect identity of the two refractions, in the direction of the supposed axis; or, in the language employed by Mr Biot with respect to mica, the existence of a double axis of extraordinary refraction: and it is the more credible that such a slight irregularity may have existed in the sulfate of lime without having been observed, as Dr Brewster has lately detected a similar property in the arragonite, though both Malus and Biot had examined this substance very carefully without being aware of it. The calculation of the extraordinary refraction, in such a case, would afford but little additional difficulty, if its characters were well determined: the form, in which the undulations must be supposed to diverge, might properly be termed an *amygdaloid*; and the velocities with which the sections, formed by the given surface, would extend themselves, might be deduced from the properties of the ellipsis, nearly in the same manner as they have been determined for the spheroid. The difference of the results of the calculation from the spheroid, and of Mr Biot's experiments, or rather of the empirical formula, derived from them, may be seen in the subjoined table; the first part of which, deduced from the theory, is applicable to all substances affording a regular extraordinary refraction, when the axis is either perpendicular or parallel to the surface of the plate. The first column of decimals shows the equivalent variation of thickness where the axis is per-

pendicular to the plate, being equal to $\frac{gg}{\sqrt{(1-gg)}}$, the

product of the sine and tangent of refraction; the second represents the variation for an ordinary thin plate, being proportional to the cosine $\sqrt{(1-gg)}$; and the subsequent columns are found by adding to the numbers of the second column those of the first, multiplied by k^2 , the square of the sine of the inclination of the plane of incidence to the axis, since

$$\frac{1-hhgg}{\sqrt{(1-gg)}} = \sqrt{(1-gg)} + \frac{k^2}{\sqrt{(1-gg)}}$$

There are also some circumstances in the experiments of Mr Biot on plates of rock crystal cut perpendicularly to the axis, which cannot be sufficiently explained on any hypothesis, without some further investigation. These plates seem to transmit the beam of light subjected to the experiment, without materially altering its polarisation, and then to produce different colours, according to the situation of the substance subsequently employed for analysing the light: so that Mr Biot supposes the rays of light to be turned more or less by the crystal, round an axis situated in the direction of their motion; and he has observed some similar effects in oil of turpentine, and in some other fluids. But it is highly probable, that all these phenomena will ultimately be referred to some simpler operation of the general law of interference.

Dr Seebeck and Dr Brewster have discovered appearances of colours, like those of doubly refracting substances, in a number of bodies which can scarcely be supposed to possess any crystalline structure. They are particularly conspicuous in large cubes of glass, which have been somewhat suddenly cooled, so that their internal structure has been rendered unequal with regard to tension. The outside of a round mass, thus suddenly cooled, being too large for the parts within it, must necessarily be held by them in a state of compression with respect to the direction of the circumference, while they are extended in their turn by its resistance: although in the direction of the diameter the whole will generally be in a state of tension: so that the refractive density may naturally be expected to be somewhat different in different directions, which constitutes the essential character of oblique refraction: and when the proportions of the external parts to the internal are modified by the existence of angles, or other deviations from a spherical form, the arrangement of the tensions must be altered accordingly: and there is no doubt that all the apparently capricious variations of the rings and bands of colours, which are observed, might, by a careful and minute examination, be reduced to the natural consequences of these inequalities of density, so far at least as the laws of the extraordinary refraction alone are concerned, although the variation of the light into two portions remain unexplained. Effects of the same

are produced by the temporary operation of partial changes of temperature, producing partial compression and extension of the internal structure of the substance: and even a mechanical force, if

sufficiently powerful, when applied externally in a single direction, has been shown, by the same observers, to produce a double refraction; although the difference of the densities, thus induced, is much too minute to be perceived in any other way, than by means of these colours, which are, in general, so much the more easily seen, as the cause which excites them is the feebler.

Dr Brewster has also shown, that the total reflection of light within a denser medium, and the brilliant reflection at the surfaces of some of the metals, are capable of exhibiting some of the appearances of colour; as if the light concerned were divided into two portions, the one partially reflected in the first instance, the other beginning to be refracted, and caused to return by the continued operation of the same power. In the case of silver and gold, it has already been observed, that there appear to be two kinds of reflection, occasioning opposite polarities; and these may possibly be concerned in the production of this phenomenon. The original interval appears to be extremely minute, but it is capable of being increased by a repetition of similar reflections, as well as by obliquity of incidence. Mr Biot has also found that such surfaces, combined with plates of doubly refracting substances, either increase or diminish the equivalent thickness, according to the direction of the polarisation which they occasion. In these and in a variety of similar investigations, a rich harvest is opened, to be reaped by the enlightened labours of future observers; and the more difficulty we find in fully explaining the facts, upon the general principles hitherto established, the more reason there is to hope for an extension of the bounds of our knowledge of the optical properties of matter, and of all the laws of nature connected with them, when the examination of these apparent anomalies shall have been still more diligently pursued.

SECTION XVI.—Of the Nature of Light and Colours.

Notwithstanding the acknowledged impossibility of fully explaining all the phenomena of light and colours by any imaginable hypothesis respecting their nature, it is yet practicable to illustrate them very essentially, by a comparison with the known effects of certain mechanical causes, which are observed to act in circumstances somewhat analogous; and as far as a theory will enable us to connect with each other a variety of facts, it is perfectly justifiable to employ it hypothetically, as a temporary expedient for assisting the memory and the judgment, until all doubts are removed respecting its actual foundation in truth and nature. Whether, therefore, light may consist merely in the projection of detached particles with a certain velocity, as some of the most celebrated philosophers of modern times assert, or whether in the undulations of a certain ethereal medium, as Hooke and Huygens maintained, or whether, as Sir Isaac Newton believed, both of these causes are concerned in the phenomena; without positively admitting or rejecting any opinion as demonstrably true or false, it is our duty to inquire what assistance can be given to our conception and

Chromatics. recollection, by the adoption of any comparison, which may be pointedly applicable even to some insulated facts only. It has however been thought desirable to separate this investigation, as much as possible, from the relation of the facts, in order to avoid confounding the results of observation with the deductions from mere hypothesis; an error which has been committed by some of the latest and most meritorious authors in this department. It may be objected to some of the preceding sections, that this forbearance has not been exercised with respect to the general law of interference and its modifications: but it would have been impossible to give any correct statement of the facts in question, without determining whether the appearances depend upon one or both of the portions of light supposed to be concerned.

Art. 1. (Sect. I.) The separation of colours is explained, in the hypothesis of emission, by the supposition of an elective attraction, different in intensity for the different rays of the spectrum: but for this difference no ulterior cause is assigned. Any original difference of velocity is contrary to direct experiment; and even the alterations of relative velocity, which must inevitably be occasioned by a variety of astronomical causes, have not been detected by the most accurate observations, instituted for the express purpose of discovering them: so that it has been suggested, that there may possibly be a multitude of rays of the same colour, moving with various velocities, and only affecting the sense when they have the velocity appropriate to that colour in the eye. The name of elective attraction is indeed little more than a mode of expressing the fact, without referring it to any simpler mechanical cause: and in chemical elective attractions the substances concerned are under very different circumstances, with respect to contact, and with respect to the probable influence of the form and bulk of their integral particles; at the same time it seems impossible to show any absurdity in the supposition of the existence of such an elective attraction with regard to the different kinds of light. On the other hand, if we consider colours as depending on a succession of equal undulations, of different magnitudes as the colours are different, we may discover an analogy, somewhat more approaching to a mechanical explanation, in the motions of waves on the surface of a liquid: the largest waves moving with the greatest rapidity, although the approximate calculation, derived from the most approved theory, leads us to the same expressions for the velocity, as are applicable to the transmission of an impulse through an elastic fluid. The fact is, that a larger wave moves more rapidly than a smaller, because the pressure is not precisely limited to a perpendicular direction, as the simplest calculation supposes, but operates also more or less in an oblique direction, principally within a certain angular limit; so that the utmost depth, at which any difference of pressure can affect the liquid as a motive force, is that at which this angle may be imagined to comprehend virtually the exact breadth of a wave; and since the velocity depends on the depth of the fluid affected at once by the pressure, the breadth becomes in this manner an

element of the determination. Thus also the larger **Chromatics.** undulations, constituting red light, are found to move more rapidly than those of the violet, which are supposed to be smaller; and there are many ways in which the difference may be supposed to be occasioned, although not depending exactly on the same cause as in the case of the waves on the surface of a liquid. It is well known that sounds of all kinds move with an equal velocity through the air; and all colours arrive through the supposed elastic ether in the same time from the remotest planets: but a refractive medium, however transparent, is not to be considered as perfectly homogeneous: in many instances, two mediums, of different qualities, seem to pervade every part of a crystal, which is completely uniform in its appearance; and it seems to be necessary, in every case, to suppose the particles of material bodies scattered at considerable distances through a medium which passes freely through their interstices; so that we may conceive the undulations of light to be transmitted partly through the particles themselves, and partly through the intervening spaces, the two portions meeting continually after a certain very minute difference in the length of their paths: we may then suppose the portion transmitted through the interstices to be weakened by the irregularity of its passage, which will affect the smaller undulations more than the larger: and when these portions are combined with the portions more slowly transmitted through the particles themselves, these last will bear a greater proportion to the former in the violet than in the red light, and will have more influence on the ultimate velocity, which will therefore be smaller for the violet than for the red. This explanation may perhaps be far from the best that the hypothesis in question might afford; but it will serve as an illustration of a possible mode, in which the phenomenon may be referred to the established laws of mechanics, without the continual introduction of new principles and properties.

Art. 2. (Sect. IV. A.) Most of the ordinary phenomena of optics are capable of a sufficiently satisfactory explanation, on either of the hypotheses respecting the nature of light and colours: but the laws of interference, which have been shown to be so extensively applicable to the diversified appearances of periodical colours, point very directly to the theory of undulation: so directly, indeed, that their establishment has been considered, by many persons on the Continent, as almost paramount to the establishment of that theory. It might not, however, be absolutely impossible, to invent some suppositions respecting the effects of light, which might partially reconcile these laws to the theory of emission. Thus, if we suppose, with Newton, the projected corpuscles of light to excite sensation by means of the vibrations of the fibres of the retina and of the nerves, we may imagine that such vibrations must be most easily produced by a series of particles following each other at equal distances, each colour having its appropriate distance in any given medium: it will then be demonstrable, that any second series of similar particles, interfering with them, in such a manner as to bisect their intervals, will destroy their effect

Chromatics. in exciting a vibratory motion; each succeeding particle meeting the fibre at the instant of its return from the excursion occasioned by the stroke of the preceding, and thus annihilating the motive effect of that stroke. But the illustration ends here: for it seems impossible to adapt it to the greater number of the alternations which occur, during the passage of a ray, through a given space, in a denser medium: since it is an indispensable condition of the projectile theory, that the velocity of light should be increased upon its entrance into a medium of greater refractive density. The Newtonian theory, of fits of easy reflection and easy transmission, is still more limited in its application; since it attributes to one portion of light those effects, which have been strictly demonstrated to depend on the presence of two.

In the undulatory theory, the analogy between the laws of interference, and the phenomena of the tides, and the effects of the combination of musical sounds, is direct and striking. The existence of an undulation of an elastic medium depends on the recurrence of opposite motions, alternately direct and retrograde, at certain equal distances, in the same manner as a series of waves consists in a number of alternate elevations and depressions, and the succession of the tides in a number of periods of high and low water. The spring and neap tides, derived from the combination of the simple solar and lunar tides, afford a magnificent example of the interference of two immense waves with each other: the spring tide being the joint result of the combination when they coincide in time and place, and the neap when they succeed each other at the distance of half an interval, so as to leave the effect of their difference only sensible. The tides of the port of Batsha, described and explained by Halley and Newton, exhibit a different modification of the same opposition of undulations; the ordinary periods of high and low water being altogether superseded, on account of the different lengths of the two channels by which the tides arrive, affording exactly the half interval which causes the disappearance of the alternation. It may also be very easily observed, by merely throwing two equal stones into a piece of stagnant water, that the circles of waves, which they occasion, obliterate each other, and leave the surface of the water smooth, in certain lines of a hyperbolic form, while, in other neighbouring parts, the surface exhibits the agitation belonging to both series united. The beating of two musical sounds, nearly in unison with each other, appears also to be an effect exactly resembling the succession of spring and neap tides, which may be considered as the beatings of two undulations, related to each other in frequency as 29 to 30; and the combination of these sounds is still more identical with that which this theory attributes to light; since the elementary motions of the particles of the luminiferous medium are supposed to be principally confined to the line of direction of the undulation, while the most sensible effects of the waves

termed immediately on their ascent and descent, in direction perpendicular to that of their progressive motion.

Art. 3. (Sect. IV. B.) The diminution of the velocity of light upon its entrance into a denser me-

dium, in the direct proportion of the refractive density, is one of the fundamental principles of the undulatory theory, and is perfectly inadmissible on the supposition of projected corpuscles. But it must be remembered, that the demonstration of the actual existence of this proportion is somewhat indirect; being only derived from the necessity of admitting it, in the application of the laws of interference to the observed phenomena: and we have no means of obtaining an immediate measure of the velocity of light in different mediums.

Chromatics. Art. 4. (Sect. IV. C.) The loss of the half interval may be explained, in particular cases, without difficulty, although, in other instances, the circumstances are too complicated to allow us to appreciate their effects. In the direct transmission of a ray of light through a plate of a transparent substance, we may compare the denser medium to a series of elastic balls, larger and heavier than another series in contact with them on each side. Now, it is well known that a series of elastic balls transmits any motion from one end to the other, while each ball remains at rest, after having communicated the motion to the next in order; so that the last only flies off, from having none beyond it to impel: and if the balls, instead of being only possessed of repulsive forces, were connected by elastic ligaments of equal powers, a motion in a contrary direction would be transmitted with equal ease; the last ball, being retained by the ligament, instead of flying off, would draw the last but one in the same direction, itself remaining at rest after this negative impulse; and the motion would be communicated backwards in the same manner throughout the series to the first ball; and then, for want of further resistance, this ball would not remain at rest after receiving the negative impulse, but would be drawn forwards by it, so as to strike the second, precisely in the same manner as at the beginning of the experiment; and this second positive impulse would proceed through the whole series like the first. Such is the nature of the longitudinal vibrations of elastic rods, first observed by Chladni; the cohesion of the substance supplying the place of the supposed elastic ligaments: and in the case of an elastic fluid, the pressure of the surrounding parts performs the same office; a negative impulse being always propagated through it with the same facility as a positive one. If, instead of a single series of balls, we now consider the effect of two series, the second consisting of larger balls than the first, the last ball of the smaller series will not remain at rest after striking the first of the larger, but will be reflected, so as to strike the last ball but one in a retrograde direction; and this retrograde impulse will be continued to the first ball, constituting a positive impulse with respect to the new direction, in which it is propagated. But if the first series of balls be larger than the second, the last of the larger balls will not be deprived of all its motion by striking the first of the smaller, but will continue to move more slowly in its first direction; and the elastic ligaments will then be called into action, so as to carry back, step by step, to the first ball, this remaining impulse, which will become negative with respect to the new direction of its transmission. And the same must

Chromatics. happen in the case of two elastic mediums in contact, supposing them to be of equal elasticity, but of different densities; the direction of the elementary motions either coinciding with that of the general impulse, or being opposite to it in both mediums at once, when the reflection is produced by the arrival of the undulation at the surface of a denser medium, and being reversed when at the surface of a rarer: and it is obvious that such an inversion of any regular undulation is paramount to its retardation or advancement, to the extent of half of the interval which constitutes its whole breadth; every affection of such an undulation being precisely inverted, at the distance of half the breadth of a complete alternation: and these effects will not materially differ, whether the impulse be supposed to arrive perpendicularly at the surface, or in an oblique direction.

Art. 5. (Sect. IV. D.; Sect. XIII.) The experiments of Mr Arago, not yet published in detail, which show that light does not interfere with light polarised in a transverse direction, lead us immediately to the consideration of the general phenomena of polarisation, which cannot be said to have been by any means explained on any hypothesis respecting the nature of light. It is certainly easier to conceive a detached particle, however minute, distinguished by its different sides, and having a particular axis turned in a particular direction, than to imagine how an undulation, resembling the motion of the air which constitutes sound, can have any different properties, with respect to the different planes which diverge from its path. But here the advantage of the projectile theory ends; for every attempt to reduce the phenomena of polarisation to mechanical laws, by the analogy of magnetism, has completely failed of enabling us to calculate the results of the actions of the forces, supposed to be concerned, in any correct manner: to say nothing of the extreme complication of the properties, which it would be necessary to attribute to the simplest and minutest substances, in order to justify the original hypothesis of a polarity, existing in all the particles of light, and a directive attraction, that is, a combination of attraction and repulsion, in every reflecting or refracting substance. In the undulatory theory, we may discover some distant analogies, sufficient to give us a conception of the possibility of reconciling the facts with the theory, and perhaps even of reducing those facts to some general laws derived from it: although it will be necessary, in this intricate part of the inquiry, to proceed analytically rather than synthetically, and to rest satisfied for the present, without bringing the analysis to a termination by any means explanatory of all the phenomena. Some of the supporters of this theory may perhaps be of opinion, that its deficiencies are too strongly displayed by this attempt: but it is for them to find a more complete solution of the difficulties, if any such can be discovered.

In the case of a wave, moving on the surface of a liquid, considering the motion of the particles at some little distance below the surface, as concerned in the propagation of an undulation in a horizontal direction, we may observe that there is actually a lateral motion, throughout the liquid, in a plane of

Chromatics. which the direction is determined by that of gravitation; but this happens because the liquid is more at liberty to extend itself on this side than on any other, the force of gravitation tending to bring it back, with a pressure of which the operation is analogous to that of elasticity; and we cannot find a parallel for this force in the motions of an elastic medium. It is indeed very easy to deduce a motion, transverse to the general direction, from the combination of two undulations proceeding from two neighbouring points, and interfering with each other, when the difference of their paths amounts to half an interval: for the result of this combination will be a regular, though a very minute vibration in a transverse direction, which will continue to take place throughout the line of the propagation of the joint motions, although certainly not with any force, that would naturally be supposed capable of producing any perceptible effects. There must even be a difference in the motions of the particles in every simply diverging undulation, in different parts of the spherical surface to which they extend: for, supposing it to originate from a vibration in a given plane, the velocity of the motion constituting the undulation will be greatest in the direction of that plane, and will disappear in a direction perpendicular to it, or rather will there become transverse to the direction of the diverging radii: and in all other parts there must be a very minute tendency to a transverse motion, on account of the difference of the velocities of the collateral direct motions, and of the compressions and dilatations which they occasion. When, also, a limited undulation is admitted into a quiescent medium, it loses some of its force by diffraction on each side, where it is unsupported by the progress of the collateral parts: and if an undulation were admitted by a number of minute parallel linear apertures or slits, or reflected from an infinite number of small wires, parallel to each other, it would still retain the impression of the incipient tendency to diffraction in all its parts, producing a modification of the motion, in a direction transverse to that of the slits or wires. It is true that all these motions and modifications of motion would be minute beyond the power of imagination, even when compared with other motions, themselves extending to a space far too minute to be immediately perceived by the senses: and this consideration may perhaps lessen the probability of the theory as a physical explanation of the facts: but it would not destroy its utility as a mathematical representation of them, provided that such a representation could be rendered general, and reducible to calculation: and even in a physical sense, if the alternative were unavoidable, it is easier to imagine the powers of perceiving minute changes to be all but infinite, than to admit the portentous complication of machinery, which must be heaped up, in order to afford a solution of the difficulties, which beset the application of the doctrine of simple projection to all the phenomena of polarisation and of colours. It is not however possible at present to complete such a mathematical theory, even on imaginary grounds; although a few further analogies between polarisation and transverse motion force themselves on our observation.

Chromatics.

In the theory of emission, the resemblance of the phenomena of polarisation to the selection of a certain number of particles, having their axes turned in a particular direction, supposing these axes, like those of the celestial bodies, to remain always parallel, will carry us to a certain extent, in estimating the quantity of light contained in each of the two pencils, into which a beam is divided and subdivided: but it would soon appear, that, after a few modifications, this parallelism could no longer be supposed to be preserved: we should also find it impossible to assign the nature and extent of any forces, which might be capable of changing the former directions of the axes, and fixing them permanently in new ones. The distinction of a fixed, a moveable, and a partial polarisation, which has been imagined by Mr Biot, must vanish altogether, upon considering that all the effects, which he attributes to the partial polarisation, are observable in experiments like those of Mr Knox, in which there is confessedly no polarisation at all.

If we assume as a mathematical postulate, in the undulatory theory, without attempting to demonstrate its physical foundation, that a transverse motion may be propagated in a direct line, we may derive from this assumption a tolerable illustration of the subdivision of polarised light by reflection in an oblique plane. Supposing polarisation to depend on a transverse motion in the given plane, when a ray completely polarised is subjected to simple reflection in a different plane, which is destitute of any polarising action, and may therefore be called a neutral reflection, the polar motion may be conceived to be reflected, as any other motion would be reflected at a perfectly smooth surface, the new plane of the motion being always the image of the former plane: and the effect of refraction will be nearly of a similar nature. But when the surface exhibits a new polarising influence, and the beams of light are divided by it into two portions, the intensity of each may be calculated, by supposing the polar motion to be resolved instead of being reflected, the simple velocities of the two portions being as the cosines of the angles formed by the new planes of motion with the old, and the energies, which are the true measure of the intensity, as the squares of the sines. We are thus insensibly led to confound the intensity of the supposed polar motion, with that of the reflected light itself; since it was observed by Malus, that the relative intensity of the two portions, into which light is divided under such circumstances, is indicated by the proportion of the squares of the cosine and sine of the inclination of the planes of polarisation. The imaginary transverse motion might also necessarily be alternate, partly from the nature of a continuous medium, and partly from the observed fact, that there is no distinction between the polarisations, produced by causes precisely opposed to each other, in the same plane.

Why light should or should not be reflected at certain surfaces, when it has been previously polarised, cannot, even with the greatest latitude of hypothesis, be very satisfactorily explained, but it is remarkable that the transmission is never wholly destroyed, or even weakened in any considerable pro-

portion. We might, indeed, assign a reason for the occurrence of a partial reflection or a total transmission in the constitution of the surface concerned: since every abrupt change of density must necessarily produce a partial reflection, while a gradual transition by insensible steps must transmit each impulse with undiminished energy, and without any reflection of finite intensity, as in the well known case of a collision, supposed to be performed with the interposition of an infinite number of balls of all possible intermediate magnitudes. If, therefore, we could find any modification of light, which could cause it to be transmitted from one medium to another in a more or less abrupt manner, we should thus be able to discover a cause of a variation of the intensity of the partial reflection: and this seems to be the nearest approach, that we can at present make, to an explanation of the phenomenon, according to the undulatory theory.

Art. 6. (Sect. V.) The equal intensity of the colours of thin plates, seen by reflection and by transmission, is a fact which would not have been expected from the immediate application of the law of interference, and which seems, therefore, at first sight to militate against its general adoption. But this is only one of the many modifications of the law, which are the immediate consequences of its connexion with the undulatory theory; and it may be demonstrated, from the analogy of a series of elastic bodies, that no material difference in the intensity of the two kinds of colours ought to be expected in such circumstances. The intensity of a ray of light must always be considered as proportional to the energy or impetus of the elementary motions of the particles concerned, which varies as the square of the velocity, and not simply as the velocity itself: for if the velocity were made the measure of intensity, there would be an actual gain of joint intensity, whenever a ray is divided by partial reflection: since it follows from the laws of the motion of the centre of inertia, that when a smaller body strikes a larger, not the sum, but the difference of the separate momenta, will remain unchanged by the collision, while the sum of the energies remains constant in all circumstances; the square of a negative quantity being equal to that of the same quantity taken positively. Thus, supposing an elastic ball, 1, to strike another of which the mass is r , with the velocity 1,

the velocity of the transmitted impulse will be $\frac{2}{r+1}$,

and that of the reflected, $\frac{2}{r+1} - 1 = -\frac{r-1}{r+1}$: the sum of the momenta in the opposite directions being $\frac{3r-1}{r+1}$, instead of 1, the original momentum; but

the energies, expressed by the products of the masses into the squares of the velocities will be $\frac{4r}{(r+1)^2}$,

and $\left(\frac{r-1}{r+1}\right)^2$ respectively; and the sum of these is $\left(\frac{r+1}{r+1}\right)^2 = 1$. Now, when an impulse arrives at the

Chromatics. last of a series of larger particles, and is reflected in an inverted form, if we substitute $\frac{1}{r}$ for r , the energies will be in the proportion of $\frac{4}{r}$, and $\left(\frac{1}{r}-1\right)^2$,

or of $4r$ and $(1-r)^2$, which is the same as the former: so that, according to this analogy, the subdivision of the light at the second surface of a plate must be in the same proportion as at the first. We may call this proportion that of m^2 to n^2 , m^2+n^2 being equal to 1: we have then n^2 for the energy of the first partial reflection, m^2n^2 for the second; and m^2n^4 for the third: for the first transmission, into the substance, m^2 ; for the second, out of it, m^4 ; for the third, after an intermediate reflection, m^4n^2 ; and for the fourth, after two reflections, m^4n^4 ; and the elementary velocities in either medium, compared among themselves, will be as the square roots of the respective energies. But it may be proved that, in all collisions of two moving bodies, each of the motions produces its effect on the velocities after impulse, independently of the other: so that the changes introduced, in consequence of the motion of one of the bodies concerned, are the same as it would have occasioned, if the other had been at rest; and consequently, if two undulations interfere in any manner, the joint velocities of the particles must always be expressed by the addition or subtraction of the separate velocities belonging to the respective undulations. When, therefore, the beam first partially reflected, of which the elementary velocity is expressed by n , interferes with the beam transmitted back, after reflection at the second surface, with the velocity m^2n , the joint velocity, in the case of the perfect agreement of the motions, will be $n+m^2n$, and in case of their disagreement, $n-m^2n$; the energies being $(n+m^2n)^2$ and $(n-m^2n)^2$; the difference, which is the true measure of the effect of the interference, being $4m^2n^2$, that is, four times the product of the respective velocities. But when the light simply transmitted at the second surface, with the velocity m^2 , interferes with the light transmitted after two reflections, with the velocity m^2n^2 , the quadruple product becomes $4m^4n^2$, only differing from the former in the ratio of m^2 to 1, which is that of the intensity of the light transmitted by the single surface to the intensity of the incident light, the difference being much too slight to be directly perceived by the eye; so that this result may be considered as agreeing perfectly with Mr Arago's observation.

We may also obtain, from the analogy with the effects of collision, an illustration of the intensity of the partial reflection in different circumstances; although it is not easy to say what ought to be the precise value of r in the comparison. If we imagined the two mediums to differ only in density, while their elasticity remained equal, which is the simplest supposition, the density must be conceived to vary as the square of the velocity appropriate to the medium: but the value of r , thus determined, makes the partial reflection in general much too intense, and it becomes necessary to suppose it weakened by the intervention of a stratum of intermediate density,

such as there is every reason to attribute to the surfaces of material surfaces in general, from the considerations stated in the article *COHESION* of this *Supplement*. However this may be, we shall in general approach sufficiently near to a representation of the phenomenon, by taking the mass r in the simple proportion of the refractive density: thus, in

the case of water, making $r = \frac{4}{3}$, we have for the

energy of the first partial reflection $\left(\frac{r-1}{r+1}\right)^2 =$

$\frac{1}{49} = .0204$, while the result of Bouguer's experi-

ments is .018; and the agreement is as accurate as could have been expected, even if the whole calculation had not been an imaginary structure. In the case of glass, the difference is somewhat greater; and it is natural to expect a greater loss of light from a want of perfect polish in the surface: for, taking

$r = \frac{3}{2}$, we have $n^2 = .040$, and Bouguer found the re-

flexion only .025. The surface of mercury reflected nearly .60; whence r should be about 8: whether the index of the refractive density can be so great as this, we have no precise mode of determining; but there seems to be something in the nature of metallic reflection, not wholly dependent on the density: thus it may be observed, that potassium has a very brilliant appearance, though its specific gravity is very low; at the same time, its great combustibility might give it a much higher rank among refractive substances, than could otherwise have been expected from its actual density.

Art. 7. (Sect. XIII.) Although the ingenuity of man has not yet been able to devise any thing like a satisfactory reason for the reflection of a polarised ray in one case, and its transmission in another: yet several attempts have been made, with various success, to reconcile the different hypotheses of light with the other phenomena of oblique refraction. The illustrious Mr Laplace has undertaken to deduce the laws of this refraction, according to the projectile system, from the general doctrines of motion; and he has sufficiently demonstrated, that the path followed by the light is always such, as to agree with the principle of the least action, supposing the law of the velocities previously established; or in other words, that the sum of the products of the spaces described, into the respective velocities, is always the least possible. To this demonstration it has been objected, that notwithstanding the complication of its steps, it is in fact nothing more than the simple translation of the fundamental law of Huygens into another language: for it is assumed in this theory, upon obvious and intelligible grounds, that the path of light must always be such, that the time may be equal with respect to two neighbouring collateral parts of the undulation; which is the well known condition of a minimum of the whole time employed: and the time being always expressed by the space divided by the velocity, if we suppose the proportions of the velocities to be inverted, as in the two theories

Chromatics. respecting light, the expression of the time in the one will be identical with that of the action in the other: consequently the conditions of the propagation of light, in the Huygenian doctrine, must always imply the observation of the law of least action in the opposite hypothesis: and this general proposition Mr Laplace has taken great pains to prove, with respect to a particular instance, in which the Huygenian calculation had been found, notwithstanding Newton's doubts, to agree perfectly with the phenomena. It has also been observed, that the law of the least action is wholly inadmissible as a fundamental principle of motion: that it is completely unphilosophical to multiply unnecessarily the number of postulates or elementary laws: and that although in many cases the principle may be capable of being established as a derivative proposition, yet in order to demonstrate it, we must assume that the velocity must be the same in all directions, between the same parallel or concentric surfaces, or at any rate, must limit our reasoning by conditions, incompatible with the nature of the actions, to be considered as the foundation of the laws of extraordinary refraction.

In this single point, the undulatory theory has every possible advantage over its rival. For the difference of the velocities in different directions, no force has been assigned as a cause, in the projectile system, at all more general than the individual directions of the rays with respect to the axis. But upon the hypothesis of undulations, it has been demonstrated, without any gratuitous supposition, that every lamellar or fibrous substance must transmit every diverging impulse in the form of a spheroidal surface, supposing only the elasticity to act more powerfully in one direction than another, as it naturally must do in such circumstances. (*Quarterly Review*, No. 4.) And when we consider the experiments of Dr Brewster and Dr Seebeck, which show, that any compression or extension whatever, acting in a given direction on any transparent solid, is capable of occasioning those appearances of colour, which prove the transmission of light by an ordinary and an extraordinary refraction, we cannot help imagining, that the cause of the elliptic refraction must be of a nature more simple, than is consistent with the existence of a multiplicity of attractions, and repulsions, and polarising powers, acting in all manner of directions, with every possible variation of intensity, independently of any assignable variation of the circumstances of the light affected.

Chromatics. There is however another mode of considering the mechanism of elliptic refraction, which is somewhat less simple and elementary, but which affords us a further analogy to the phenomena of polarisation by reflection and transmission. If we suppose a doubling crystal to consist of a large number of very thin plates, united by a medium differing but little from them in refractive density, this pile will completely polarise the transmitted light, as Malus and Dr Brewster have shown, in a plane perpendicular to that of the incidence, even when the inclination of the surfaces is widely different from that which produces the most complete polarisation at once: and at the same time a part of the light, partially reflected by each plate, will be again reflected by the neighbouring surfaces into its original direction; nor will it be difficult to imagine that the quantity of light thus twice reflected, may, from some unknown cause, be rendered ultimately equal to that of the light simply transmitted, which, according to the laws of polarisation, will never exceed half of the original beam. Now the lengths of the paths of these two portions will not only be different, but the difference will vary according to the direction: for while the light simply transmitted proceeds to describe its path, with the uniform velocity belonging to the mean of the two mediums, combined always in a constant proportion, the light twice reflected by each plate will be retarded most of all in the direction perpendicular to the plates, as in the case of the colours of common thin plates; and in oblique directions, the number of plates, which it has to pass through in a given space, being as the cosine of the angle of incidence, and the retardation in each plate being also as the same cosine, neglecting the difference between the angles of incidence and refraction, which is supposed to be inconsiderable, the whole retardation will be as the square of the cosine of the inclination to the axis, which is the well known proportion of the difference of the diameters of a circle, and of an ellipsis approaching near in it. We thus obtain a general idea of the combination of two effects, which do not appear to be related in any other point of view, a regular oblique refraction and a distinct polarisation; further than this the comparison is by no means completely satisfactory: and the great difficulty of all, which is to assign a sufficient reason for the reflection or nonreflection of a polarised ray, will probably long remain, to mortify the vanity of an ambitious philosophy, completely unresolved by any theory. (I. S.)

CHRONICLE, PARIAN. See the *Encyclopædia* under this head, and PARIAN CHRONICLE in this Supplement for some corrections.

CINNAMON. The plant which produces the aromatic bark called cinnamon, is described under the word *Laurus*, in the article BOTANY of the *Encyclopædia*. The following particulars are extracted from a manuscript account of the cultivation and commerce of cinnamon, written in Ceylon in 1816, by

Mr H. Marshall. The word cinnamon occurs in several passages of the English version of the *Old Testament*. Cinnamon was burnt on the funeral pile of Sylla and of Poppæa. The ancients got their cinnamon through Arabia, to which country it was brought probably from Ceylon.

In 1498, Vasco di Gama landed at Calicut, and from that time the merchandise of India, which had formerly been imported into Europe through the

Cinnamon. medium of the Venetians, took a different route, and was carried round the Cape of Good Hope by the Portuguese. The Portuguese were the first Europeans who established a factory in Ceylon. This they accomplished at Colombo, in the early part of the sixteenth century; notwithstanding the opposition of the Arabian merchants, who carried on the trade from Ceylon, and who did all in their power to prevent the establishment of the Portuguese. The Portuguese were driven from Ceylon by the Dutch in 1656, and the Dutch by the English in 1796.

The Dutch were the first who cultivated the cinnamon plant in Ceylon. They began to form plantations of cinnamon in 1765, and in 1778 Thunberg found these plantations extensive, and some of the plants or stools had already afforded bark three times. Before these plantations were formed, the Dutch were supplied with cinnamon bark from the cinnamon plants that grow spontaneously in the territory of the king of Candy, and by the sufferance of that chief. The part of the old Dutch territory between Negumbo and Matura is that which is best fitted for the cultivation of cinnamon.

Produce of
cultivated
Cinnamon.

Each cinnamon plant in the cinnamon gardens in Ceylon affords, on an average, four tenths of an ounce of bark every second year. But a cinnamon plant, in its most vigorous state, and carefully cultivated, produces 23 ounces of bark every second year.

Spontaneous
Cinnamon
Plants.

Besides the bark got from the cinnamon gardens, a considerable quantity is also collected from spontaneous plants. A great part of the interior of Ceylon is covered with trees and brushwood. Where the declivities are gentle, the cultivation of dry grain is practised. For this purpose, the trees and brushwood are cut down, the trunks and branches are burnt, and the ashes spread on the ground; and on the soil thus prepared, dry grain is sown. The roots of the trees and bushes still remain in the ground. One crop only is taken, and in a few years the ground is again covered with trees and brushwood. At the end of 15 or 20 years, the same spot is treated as before, for the purpose of yielding a crop of grain. A piece of ground cultivated in this way is called a china. Upon these chinas which have been recently cultivated, cinnamon plants of a proper age for yielding cinnamon bark are found growing spontaneously, and the bark of these cinnamon plants is collected. But the best cinnamon bark is obtained from the plants cultivated in the cinnamon gardens.

Contract
with the
East India
Company.

By the agreement made in 1802, the English Government of Ceylon engages to supply the East India Company annually with 400,000 lb. of cinnamon, at the rate of 3s. Sterling *per* lb. If any ship is found to have more than 20 lb. of cinnamon on board, without permission from the English government of Ceylon, or from the East India Company, the ship and cargo are liable to confiscation.

That there might not be produced a greater quantity than that required for the East India Company's investment, some of the cinnamon plantations were rooted out soon after the settlement came into the possession of the English. But it was afterwards found expedient to increase the produce of cinnamon; and for that purpose the cinnamon plantations were cultivated with increased attention.

The average annual exportation of cinnamon from

Ceylon, from 1804 to 1806 inclusive, was 290,018 lb.; and from 1807 to 1814 inclusive, 370,913 lb. The annual average expence was L. 14,223, or about 9d. *per* lb. The cinnamon which has not the qualities proper for the European market is rejected. Part of this rejected cinnamon is sold to merchants at about 2s. *per* lb. It is shipped for the supply of the British settlements in India. That which goes to Bombay is reexported to Jedda and Massuah. Some of it reaches England under the name of Casia.

Cinnamon

Circars.
Quantity ex-
ported from
Ceylon.

Average yearly quantity of cinnamon sold at the East India Company's sales, from 1803 to 1810 inclusive, - - - 318,258 lb.
which brought L. 95,825, about 6s. *per* lb.

According to Stavorinus, the average quantity sold by the Dutch, from 1775 to 1779, was - - - 370,000
which brought L. 203,500, about 11s. *per* lb.

The average of the Dutch sales from 1785 to Canton Cinnamon. 1791 is greater, and the price is nearly double the average English price from 1803 to 1810. The large quantity of cinnamon brought from Canton is probably the cause of the diminution in quantity, and the fall in price of the Ceylon cinnamon. The cinnamon from Canton is generally inferior in aromatic quality, but it is brought to market at a lower price than the Ceylon cinnamon. It is sold under the name of casia. It is imported into Canton from the Sooloo islands, and from Cochun-China. It does not appear that any cinnamon is produced in China.

The third quality of Ceylon cinnamon is considered equal to that brought from China, and could probably be supplied at as low a price. This quality of cinnamon might be collected in Ceylon to a great amount, and a large importation of it into the London market, sold at a moderate profit, would probably lessen the demand for Canton cinnamon.

Cinnamon grows on the Malabar coast, and was collected there in the dominion of the king of Travancore by the Dutch and the English. Of this trade, an account is given by Fra Paolo de San Bartholomeo, who resided in that country in 1776. Cinnamon is also collected in Sumatra. Bruce says, that it grows in the country between Cape Gardafan and Melinda.

In 1801, a considerable quantity of essential oil of Cinnamon. was distilled from the rejected cinnamon in Ceylon; and latterly (1816) 3000 ounces have been distilled, part of which was sent to England. But it is more profitable to sell the rejected cinnamon, than to distil the oil from it.

Casia-buds are the receptacle of the fructification of the cinnamon plant. They are imported into Europe chiefly from Canton. They might be collected abundantly in Ceylon; but this has not hitherto been done.

(V.) -

CIRCARS (NORTHERN), an extensive district of Indostan, extending about 470 miles along the coast of Coromandel, from the frontier of the Carnatic to that of Bengal. It reaches inland from 40 to 70 miles, when it is separated from the provinces of Hyderabad and Berar by a range of hills, which in the

Circars.

south are low and detached from each other, but in the north rise into high mountains, impassable for horses or carriages, unless at a single point near Salourgant. The area of the whole is estimated at 17,000 square miles, of which Mr Grant (*Appendix to Fifth Report on Indian Affairs*, p. 620) supposes one-fifth to be under cultivation. This last estimate is given as purely conjectural; and considering that the tract is generally level, and that besides maintaining a large internal population, it exports grain to a great extent, it seems scarcely possible that it should not contain a much larger proportion of cultivated land. The number of inhabitants is calculated at two millions and a half, which would give nearly 150 to the square mile.

History.

The Circars, after enjoying for many ages a native government, experienced the weight of Mahomedan power, when, in 1541, the sovereign of the empire of Beder, conquered first Condapilly, and afterwards Guntoor, with the whole district of Masulipatam. The subjection, however, was so imperfect, that, in 1571, the country was to be conquered anew. It became then attached to the dominion of Hyderabad, and along with it fell, in 1687, under the wide spread empire of Aurungzebe. That conqueror, however, absorbed in distant and more splendid objects of ambition, appears to have been satisfied with little more than a formal submission. The Circars never fully felt the yoke, till, on the breaking up of the Mogul empire, they became a portion of the kingdom founded at Hyderabad, by Nizam-ul-Moolk. These territories formed to the Nizam a more important object than they had done to the Mogul. He accordingly occupied them with a military force, and took vigorous measures for collecting the revenue. After the death of Nizam-ul-Moolk, his third son, Salabat Jung, was enabled, through the aid of the French, to obtain the sovereignty of the Circars; but when Masulipatam, in 1759, yielded to the British arms, Salabat Jung, deprived of French support, was unable to maintain his authority, and these territories reverted to the reigning Nizam. Soon after Lord Clive threw upon them an ambitious eye; and, availing himself of the obsolete claim of the Mogul, obtained from that sovereign a grant of the Circars, which, in the following year, the Nizam found it necessary to confirm. Only four of the five, however, came into the immediate occupation of the British; the fifth, Guntoor, being retained for life by Bazalet Jung, a son of the Nizam, who held it in Jaghire, so that it did not devolve to the Company till the year 1788.

Under all these revolutions, the interior administration of the Circars remained unaltered. Here, and over the greater part of the south of India, the village system has been long fully established. A village, politically considered, includes not only the inhabited spot, but a certain surrounding district, from which its subsistence is drawn. In each village, all employments, except the simple one of cultivating the ground, are performed by public servants, who receive, as the salary of their office, a certain portion of land, besides some small perquisites at the time of harvest. Of these functionaries the most eminent are, the potail, or chief, the talia and totie, two species of police officers; the

Circars.

boundary man; the superintendant of the water courses; the brahmin; the schoolmaster; the astrologer; the smith and carpenter; the poet; the musician; and the dancing girl. Under this simple form, most of these villages have, for a long series of ages, preserved not only their institutions, but even their name unchanged; they have seen, uninjured, all the storms of revolution pass over their heads. When revenue is to be raised, or even exactions levied, it is found most convenient to make the agreement with several of the leading men in the village; the sum being then collected by an arrangement among the inhabitants themselves.

This constitution prevails chiefly in the plains. The hilly districts are possessed by Zemindars, who let their lands by a sort of feudal tenure, on condition of military service. These Zemindars, unless when kept in strict subjection by a foreign power, hold in their hands the chief sway over the Circars. About the time when the province came into the possession of the British, they were supposed to have on foot no less than 41,000 troops. The Company appointed provincial chiefs and councils; but the power of the Zemindars continued nearly unbroken till 1791, when punishment was inflicted on the great Zemindar of Vizianagrim, who had oppressed and expelled many of the inferior chiefs. In 1802 and 1804, the salutary system of a permanent settlement of the territorial revenue was introduced. The administration, however, has not yet been placed on that regular and systematic footing, from which Bengal has derived such important advantages.

The climate of these provinces is, by the influence of the sea breezes, rendered cooler than most other regions placed under the same latitude. At the season, however, which immediately succeeds the vernal equinox, the heat becomes exceedingly intense, particularly in some of the sandy tracts near the sea coast. In the hilly districts, filled with marsh and jungle, the damp and heat combined generate a pestilential air, which gives rise to a dangerous malady, called the hill fever. The soil along the shore is sandy, but improves as it approaches the hills, when, at a certain height, cultivation gives place to woods and jungle. The intermediate tracts are well watered, and, though they yield only one crop in the year, yet that one is abundant. Rice and other grains are not only produced in quantity sufficient for internal consumption, but are exported to such an extent, as to make the Circars, during the northern monsoon, be considered as the granary of the Carnatic. Fruits, greens, and roots are raised with difficulty, particularly in the southern districts, owing, it is supposed, to the influence of the sea air. Sugar and cotton are not so plentiful as to render the province independent of foreign supply; but bay salt and tobacco are, to a certain extent, objects of exportation. An article capable of being turned to the most valuable account, presents itself in the noble forests of teak timber which grow upon the frontier mountains. The animal productions are confined chiefly to the useful species of sheep and horned cattle, which are produced in great abundance.

The Circars are not less eminent as a manufacturing, than as an agricultural district. The cotton fabrics which form its staple, are chiefly of two kinds.

Climate and Productions.

Manufac- tures.

Circassia. The first is fine long cloth, which forms the basis of the finest calicoes. This exquisite manufacture is chiefly carried on in the island of Nagur, formed by the two large branches into which the Godavery divides itself before entering the sea. The security here enjoyed from the ravages of war has allowed this valuable branch of industry to attain its present degree of perfection. This cloth forms the sole basis of the trade to Europe; and the annual exports thither are supposed, by Mr Grant, not to fall short in value of thirty lacks of rupees. The next fabric consists of coarser cloths, dyed with the chaya root, the madder of India, which grows in perfection in the sands annually overflowed by the Kistna. This manufacture is much more widely diffused, and the demand for it is immense, both in the interior, and in the regions to the east. The muslins of Cicacole, the woollen carpets of Ellore, and the silks of Berhampoor, form curious and elegant fabrics, but are produced in such small quantity, as to be of little commercial importance.

Commerce. The foreign trade of the Circars is chiefly carried on by the channel of Madras, to which the natives, in their small craft, convey its produce. The valuable article of piece goods, however, is chiefly exported in larger vessels from Masulipatam. In 1805, the exports to Madras amounted in grain to 17,64,040 sicca rupees; in piece goods to 5,59,146; and a variety of minor articles raised the total amount to 25,60,564 rupees. The imports, consisting of numerous small articles, did not exceed 5,91,144 rupees.

Number of the Circars. The Circars are commonly reckoned five in number, divided from each other by a succession of considerable rivers which cross the territory and fall into the sea. Cicacole, the most northerly and most extensive, is separated from the rest by the great stream of Godavery, which, after a course of upwards of 700 miles, falls here into the Bay of Bengal. Rajamundry is situated around and within the branches of the Godavery; Ellore and Condapilly occupy the space as far as the Kistna or Krishna; while Guntoor fills the interval between the Kistna and the southern boundary of the Circars. Masulipatam and the surrounding district have been recently considered as forming a sixth Circar.

Revenue. The following estimate formed by Mr Grant, of the gross revenue, in Madras pagodas of 4 rupees each, drawn, in 1783, from the different Circars, will give a tolerable idea, at least of their relative value;

Guntoor,	3,51,000
Masulipatam,	1,41,500
Condapilly,	3,18,000
Ellore,	3,41,143
Rajamundry,	5,04,052
Cicacole,	9,92,427½
	<hr/>
	26,51,122½

The Circars are chiefly known to Europeans by their sea-ports, which, however, are neither numerous nor of convenient approach. The most important by much is Masulipatam, affording the only point on the coast of Coromandel at which vessels can anchor without experiencing the inconvenience of a heavy surf. The town is very extensive and

populous, and is defended by a strong fort, viewed as the maritime bulwark of the Circars. The French had a factory here from 1669; and in 1751, they obtained possession of the town and fort, which they greatly strengthened. In 1759, the British, under Colonel Ford, took the fort by storm; Masulipatam was soon after ceded to them, and has continued in their possession ever since. Though no longer, as formerly, the principal place on the coast of Coromandel, it is still the theatre of an extensive commerce. Besides Madras, it trades on a great scale with Calcutta and with Bassora, on the Persian Gulf. The trade with Calcutta consists chiefly of imports, as rice, raw silk, shawls, rum, and sugar. That with Bassora is supported almost entirely by the export of piece goods, particularly chintzes, which, though inferior to those of Europe, are celebrated in the east, and an object of extensive demand throughout the Persian empire. The exports to Bassora in 1811-12 amounted to 1,299,000 rupees, while the total exports did not exceed 2,136,000. See *Fifth Report on Indian affairs.* (n.)

CIRCASSIA, a country of Asia, situated on the northern declivity of that great mountain range which, under the appellation of Caucasus, fills the space from the Caspian to the Black Sea. This territory extends across from sea to sea, and northward to the rivers Terck and Cuban. Nothing can be more striking than the approach to this region, when from the *steppe*, or immense level plain to the north, is seen, abruptly rising, the vast mass of the Caucasian mountains. Four distinct groups are clad in perpetual snow, and, above all, towers the stupendous Elbrus, which rivals Mont Blanc in magnitude. The lower intervening range, called the Black Mountains, is very precipitous, and has the appearance of a regular wall. These mountains are not supposed to exceed half the elevation of the Elbrus. At the foot of these stupendous ranges lie a number of fertile and beautiful vallies, which not only feed numerous flocks and herds, but yield, in abundance, maize and millet, the grains chiefly cultivated in this part of the world.

The people by whom this picturesque region is inhabited, present moral and physical features not less remarkable than those of the spot which they occupy. The name of Circassians is a corruption of the Russian term of Tcherkess or Tcherkessians. Neither of these names, however, is known or recognized within the region itself; and, indeed, there is no foundation for our idea of the Circassian territory being inhabited by any single nation. It is filled with a number of small, separate, and hostile tribes, many of whom do not even understand each other's language. Among the most remarkable are the Kabardines, Great, and Little; the Abasses, the Kisti, the Ossetes, with many others, whose names it were needless to enumerate. As they all, however, agree in their general aspect, and are included by the Russians under one name, our object and limits will rather lead us to delineate their common features, than to enter into a tedious delineation of such as are peculiar to each.

Of all the nominal vassals of the Russian empire, the Circassians are in the most imperfect state of subjection. In the archives of the Czars, indeed,

Circars
Circassia.

Situation
and Extent.

Different
Tribes of
Inhabitants.

Circassia. acknowledgments of dependence are found as early as the commencement of the present century; but these were granted only in return for temporary aid against attacks from the Tartars of the Crimea, and never led to any farther consequences. Even now, when Russia has established herself in such force on the Caspian, she has not succeeded in reducing these tribes to any form of regular subjection. They own themselves, indeed, her vassals, but they neither pay tribute, nor perform any species of military service. On the contrary, they make regular incursions into the Russian territory, from which they carry off booty, particularly cattle, in large quantities. To check these inroads, indeed, a line has been drawn along the northern boundary of the Terek and the Cuban; it has been strengthened by the fortresses of Modok and Georgiewsk; and the severest punishments have been denounced against such of the Circassians as should transgress this limit. These threats, however, not being put into rigorous execution, the offence continues to be annually repeated. Potemkin endeavoured to conciliate the people by granting titles and presents, and even by raising some of them to the rank of Russian princes; but such favours were, by those proud chiefs, only viewed as new proofs of their invincible prowess, and they became but the more daring in their depredations. At present it is impossible to go with safety even a few miles beyond the frontier fortresses. The Circassians may, indeed, complain on their side of encroachment; since, prior to the present extension of Russian power, they had extended their sway over the greater part of the level country, which extends northward as far the Kuma.

Government
and Political
State.

From the causes now noticed, the Circassians, in the face of this great and ambitious power, have preserved entire their political independence, with all the habits of their domestic and military life. Circassia presents now nearly the same picture which was exhibited by Europe during the twelfth century. No general authority exists: the power is entirely in the hands of the chiefs, each of whom holds sway over a certain number of vassals. The pride of birth prevails to a degree scarcely equalled by any other nation. The Circassians may be generally divided into four classes. 1. The Princes, who exercise the sovereign authority, each within his own limits. 2. The Uzdens or nobles, who, with their vassals, attend the prince in war or plundering excursions, but, in the common train of affairs, are nearly independent of him. 3. The Freedmen, either of the princes or uzden, who, by manumission, are considered as having attained to the rank of uzden, but are still bound to their former master, so far as relates to military service. 4. The Vassals, who are held by the uzden in the most complete subjection, and are employed either in agriculture or in menial offices. Over this degraded class, the masters possess the power both of life and death, and of selling them into slavery, which, however, is said by Pallas to be rarely exercised. A friend of ours saw a Circassian prince bring into Ekaterinodar several slaves to sell, with their eyes bandaged, and a leathern thong covering their mouth. He professed to have taken them in war; but the circumstances induced a strong suspicion that they were his own vassals, and

that these precautions were adopted to prevent a discovery. It thus appears, however, that he was ashamed of selling his own people.

The Circassians are eminently distinguished by their physical qualities; among which beauty of form, so rare among barbarous tribes, holds a conspicuous place. The men are tall, of a thin but very athletic shape; they have expressive features, a haughty and martial air. The females possess a peculiar elegance of form and delicacy of complexion, which has long been celebrated throughout Europe, and which the admirable productions of Mr Allan's pencil have lately rendered familiar to the eye of persons of taste in this country. This Scottish artist resided for some time among the Circassian tribes. Females in Circassia appear to be less immured than in most eastern countries; at the same time they are equally exempted from any severe labour, and their face is carefully shaded from the action of the sun. The most studious care is taken to preserve the elegance of their form. Their food, when young, consists entirely of milk and pastry, of which too they receive only a limited allowance. They never go from home without wearing a species of wooden clogs to preserve the feet clean and dry, and the hands are carefully covered with gloves. One of the most remarkable appendages is a broad leathern girdle, which, at the age of ten or eleven, is fastened with silver clasps, and is never taken off till after marriage, when the bridegroom, with a sharp instrument, cuts this gordian knot, often not without danger. The face is painted only by those who bear an equivocal character.

The pride of this people is manifested by the contempt with which they treat those domestic ties and affections, which are most cherished by the rest of mankind. The husband never sees his wife, unless in the most mysterious privacy; he considers it as an insult that any one should ask for her health, or even name her in his presence. The arrangements with regard to children are still more extraordinary. At the age of three or four, they are separated from their parents; the care of rearing them is undertaken by an uzden, of the same rank with the father, but who, from some tie of dependence or obligation, is induced to undertake this office. On him devolves the whole charge of their support, education, and instruction, nor does the parent ever see them till they are presented to him at full age, and completely accomplished in all manly exercises. The foster-father depends for reward chiefly on the gratitude of his pupil, who naturally regards him with at least equal attachment as his natural father. The female children are in like manner placed under the care of the uzden, who, after completing their education, provides for them a suitable husband; and they are never seen by the father till after marriage. In a country where such paramount importance is attached to birth, unequal marriages are not only held in abhorrence, but are entirely unknown. The prince invariably marries the daughter of a prince, the uzden that of an uzden. Polygamy, though permitted by law, is not carried to any great extent, and the female sex appear to occupy a higher place in society, than in most of the other Asiatic countries.

Manners,
Customs,
and Occupation.

Circassia.

The Circassian nobles spend their time almost exclusively in hunting, feasting, and in expeditions for war and plunder. Their chief pride is their arms, on which they often expend large sums; indeed the value of a suit of complete armour for a nobleman of high rank is estimated at 2000 rubles. Those chiefly used are a bow and quiver, which are fastened round the waist and hang down on the thigh; a musket and pistols, ornamented with silver, sometimes even with pearls and precious stones; a helmet and arm-plates of polished steel; and, above all, a coat of mail, composed of polished steel rings. This last is often of such excellent quality, that the discharge of a loaded pistol will not penetrate it. The Circassian never moves abroad without these accoutrements; and a great part of his time is spent in keeping them perfectly bright and clean. The next and nearly equal object of pride is their horses. Beauty is here attempted to be combined with fleetness, strength, and the capacity of enduring fatigue; qualities extremely necessary in the light expeditions in which they are habitually engaged. Every great man has a race of horses belonging to himself, the genealogy of which is conceived to be only second in importance to that of the family. At the birth of a foal, a mark, indicating its pedigree, is burnt upon the thigh, to alter or falsify which mark is considered as a capital offence.

Among the passions, that of revenge prevails, as in all barbarous societies, where no regular forms of justice being established, each individual must vindicate his own cause. The rights of hospitality are held equally sacred, as among all other nations in a similar state of society. A Circassian chief, having received a stranger under his roof, or given him a promise of protection, will defend him even at the hazard of his own life. The firmest pledge which can be given is, that of allowing him to suck a mouthful of milk from the breast of the wife, after which he is considered as one of the family, and his wrongs or death to be avenged to the same extent as if he had really belonged to it.

About the middle of the last century, the Circassians were induced to embrace the religion of Mahomet. They are far, however, from being rigorous votaries, though the precepts of the Koran have induced some alteration on their former habits. They abstain from brandy, tobacco, and hog's flesh; they marry earlier, and polygamy has become somewhat more common.

Agricultural industry has made only a small progress among the Circassians. They raise chiefly millet, with a small proportion of barley and maize; the first-mentioned grain supplies them with bread and with a fermented liquor; and, in case of necessity, is given to their horses. Their only manure is formed by burning the herbage upon the land which they mean to sow. After raising crops for two or three years on the same ground, till it is exhausted, they abandon it, and break up another spot. The animals chiefly reared are sheep, which are valuable, though not equal to those of the Calmucks. Oxen are used chiefly for the plough, or for draught. From the vicinity of hostile tribes, it is seldom safe to carry on even the common operations of husbandry. Men are often seen driving the plough,

"clad in complete steel," and ready at the slightest signal to fly to arms. The rearing of bees is a considerable article of industry, and some possess no fewer than 300 hives.

It is difficult to ascertain the precise amount of the population of the Circassian tribes. Pallas supposes the number capable of bearing arms to be, of uzdens 1500, and of their vassals 10,000, but this estimate can include only a few of the tribes. He conceives that these troops, if they could be induced to submit to regular discipline, and to enlist in the Russian armies, would form the best light cavalry in the world.

(To the information derived from the *Travels* of Pallas and Klapproth, we have been enabled to add that of an intelligent friend, who penetrated into Circassia, and resided for some time among these tribes. (B.)

CIRRIPEDES, from *cirrus* and *pes*, signifying Derivation. curled legs, a class of animals comprehending the *barnacles* and *acorn-shells* of English naturalists.

Their nervous system consists of a series of ganglia, Characters. connected longitudinally by a double nervous cord.

They have a heart and circulating vessels.

The organs of respiration are a sort of branchiæ attached to the base of the legs.

The legs are twelve in number, and are terminated by many-jointed compressed appendices, which in the five anterior pairs are much elongated and ciliated beneath.

Their head is not distinct from the body, and there are no distinct organs of vision; the mouth consists of an upper lip; a pair of mandibles; a pair of maxillæ, each of which is furnished with a fleshy kind of palpus; and a lower lip, evidently formed by the union of the exterior maxillæ.

The intestinal canal is simple, and not contorted or furnished with cæca; it terminates at the base of a long proboscis-like tube. The stomach is often enlarged, and furnished with appendices.

Their organs of generation terminate at the extremity of the proboscis-like tube mentioned above.

They are hermaphrodite and oviparous.

Their food is unknown.

Many of the genera are well defined in the works of History. the older naturalists; but they have not been adopted by the moderns.

Linné arranged all the **CIRRIPEDES** under the generic name *Lepas* (a term applied to the *limpet* by the ancients), and named the animal *Triton*.

The great divisions of these animals are very obvious, and have been distinguished in common language, as well as by several authors, who named them *Lepas* and *Balanus*.

Lamarck, in 1812, first established the **CIRRIPEDES** as a distinct class, which has been adopted by Cuvier and Blainville, who consider it to constitute a distinct subtype of molluscous animals.

We regard them as belonging to the type *anrulosa*, since they agree with those animals in every point of essential structure.

John Hunter was well acquainted with their organs of respiration, digestion, and generation, as may be learnt from an inspection of the preparations of those parts, preserved in his superb collection of comparative anatomy.

Poli. Cuvier, and Home, have likewise treated on the structure of the **CIRRIPEDES**.

Circassia

Cirrripedes.

CLASSIFICATION.

GENERA.

Order I. CAMPYLOSOMATA. Base of the body tendinous and flexible: upper part with shelly plates; the legs passing through a slit in the anterior part.	Fam. I. CLYTIDII. Upper part of the body not much compressed, membranaceous, with very small shelly or corneous plates.	Summit of the body with two cylindric hollow processes. Summit of the body simple.	1. OTION. 2. CINERAS.
	Fam. II. POLICIPIDII. Upper part of the body very much compressed, and covered with shelly plates.	Thirteen in number: base with hairy wrinkles, the interstices hairy. Five large and many small: base with shelly scales.	3. PENTALASMIS 4. SCALPELLUM. 5. POLLICIPES.
Order II. ACANTOSOMATA. Whole body surrounded by a shell of one or more parts. Legs passing out through the operculum which closes the upper part of the shell.	Fam. I. CORONULIDII. Operculum fleshy and protuberant: Shell sex-partite, with its base open.	Shell subcylindric, narrower at its base: operculum protected by four large equal-sized shelly valves.	6. TUBICINELLA.
		Lips of operculum, very prominent, with two large shelly valves before, and one small one on each side of the legs. Operculum protected by four large equal-sized shelly valves.	7. CORONULA.
		Shell with its base much wider than its apex.	8. CHELONOBIA.
	Fam. II. BALANIDII. Operculum compressed, bivalve, and shelly: base closed by shelly matter.	Shell undivided: valves of operculum bipartite.	9. PYRGOMA.
		Base cup-shaped or infundibuliform.	10. CREUSIA.
		Shell four-partite: valves of operculum undivided.	11. ACASTA
		Shell sex-partite: valves of operculum bipartite.	12. BALANUS.
		Base of the form of the substance to which it adheres.	13. CONIA.
		Shell four-partite: valves of operculum undivided.	14. CLISIA.

Order I. CAMPYLOSOMATA.

LILPAS, *Linné*, *Pennant*, *Poli*, *Montagu*, &c.ANATIFA, *Lamarck*, *Cuvier*, &c.

VOL. III. PART I.

Base of the body produced into a tendinous, flexible peduncle, which is composed of two coats, which pass downwards from the upper part. The interior coat is lined by longitudinal muscular fibres, and the cavity

Cirripedes. is filled by cellular matter, one side of which is traversed by a longitudinal cylindric vessel. The base of the peduncle generally spreads a little, and is closed over by the tunics.

The upper part of the body is covered by three coats; the outer one is hardest, and has generally shelly matter deposited on it. The interior coat does not pass down over the peduncle, but is confined to the upper part, and surrounds the automatic organs, and the legs, which pass out through a longitudinal slit on the anterior side of the body.

Family I. CLYTIDII.

Gen. CONCHODERMA, *Olfers*.

Upper part of the body not much compressed; the scales small; two on each side below the legs; two on the summit, and one behind.

Gen. 1. OTION, *Leach*. AURITELLA, *Blainville* MSS.

Upper part of the body abruptly clavate with two cylindrical fleshy processes on the summit.

Sp. 1. *Blainvillii*. All the scales shelly; those on the summit very small, linear; hinder one very minute.

Lepas cornuta. *Montagu*, *Trans. Linn. Soc.* xi. 179. t. 12. f. 1. Plate LVII.

A single specimen was found in the bottom of a transport that was stranded on the coast of Devon. The colour, whilst living, was whitish, spotted and streaked with brownish purple.

It seems to be distinct from the *Lepas leporina*, *Poli*, tab. vi. f. 21.

Sp. 2. *Cuvieri*. Scales beneath the legs shelly; other scales corneous.

Lepas aurita. *Cuvier*, *Mem. du Mus.* ii. pl. 5. f. 12.

Mr Comyns sent us a specimen that was taken on the Dawlish coast in Devon, where it was most probably brought on the bottom of a ship.

Gen. 2. CINERAS. Upper part of the body gradually clavate, with the summit simple.

Sp. 1. *Vittata*. Pale bluish purple, with three pale bluish purple stripes on each side of the body.

Lepas membranacea. *Mont.* *Trans. Linn. Soc.* xi. 182. t. 12. f. 2. Plate LVII.

This species has been taken on the southern coast of Devon by Mr Gibbs, and by C. Loscombe, Esq. of Exmouth. We suspect, however, that it was introduced into our seas by foreign vessels, as they are not unfrequently found adhering to the bottoms of transports and merchant vessels. It differs from *Lepas coriacea*, *Poli*, Tab. vi. f. 20., in the form of the scales beneath the legs.

We have seen two other species of *cineras*, one adhering to a *hydrys* in the collection of John Hunter, the other in the collection of animals formed in the expedition to Congo, by Mr J. Cranch.

Family II. POLICIPEDIDII.

Upper part of the body very much compressed, and covered entirely by shelly plates.

Gen. 3. PENTALASMIS, *Hill*.

Upper part of the body with five scales; lower ones very large; upper ones elongate, acuminate behind; hinder ones linear curved; peduncle naked.

* *Hinder scale gradually curved; peduncle long.*

This division comprehends *Lepas unatifera* of Linné, and several species that have been confounded with it.

** *Hinder scale gradually curved; peduncle very short.* *Cirripedes*

Pentalasmis sulcata, Plate LVII. *Lepas anserifera* *Poli*, *Lepas sulcata* *Montagu*; a species common on the southern coast of Devon adhering to cuttle-bone. *Lepas muricata* *Poli*, tab. vi. f. 23-24. together with several sulcated species, which generally attach themselves to porous bodies, belong to this section.

*** *Hinder scale angulated; peduncle very short.*

Lepas fascicularis with a very diaphanous shell, is the only species of this section that we have observed.

Gen. 4. SCALPELLUM.

Upper part of the body with thirteen scales; the hinder one linear; the upper ones semicircular; the five lower ones on each side (occupying the place held by the two lower ones in *Pentalasmis*) small; peduncle with corneous wrinkles, the interstices hairy.

Sp. 1. *Vulgare*. Hinder scale carinated and subangulated. Plate LVII.

Lepas scalpellum, *Linné*.

Inhabits the Mediterranean and British Seas, adhering to coralline substances, and to the tubes of marine vermes.

Gen. 5. POLLICIPES, *Hill*.

Upper part of the body with five large scales, and several smaller ones at their base; upper scales, and that on each side below the legs largest; hinder one acuminate above; peduncle scaly; scales testaceous.

Sp. 1. *Cornucopia*. Peduncle imbricated with scales; the scales pointing upwards and rounded at their extremities; scales of the upper part of the body smooth and whitish.

Lepas pollicipes of authors. Plate LVII.

This species is said to inhabit the Norwegian Seas. It has been taken in the Firth of Forth, near Leith, and was probably brought there attached to the bottom of a ship.

Sp. 2. *Smythii*. Peduncle, with irregular scales; the interstices membranaceous; scales of the upper part of the body smooth; in the old state antiquated.

Inhabits Teneriffe, where it was discovered by the late Professor Smyth of Christiania, who gave us a large groupe of them.

Sp. 3. *Tomentosus*. The whole body tomentose. Plate LVII.

The locality of this species, which is preserved in the British Museum, is unknown.

Lepas mitella, *Linné*, probably belongs to the genus POLLICIPES.

Order II. ACAMPTOSOMATA.

Body surrounded by a shell, composed of one or more parts, which are connected by sutures; upper part open and closed by a fleshy or bivalve testaceous operculum, through which the legs pass out.

Family I. CORONULIDII.

Operculum fleshy and prominent. Shell sex-partite, open below.

The animals of this family attach themselves to the bodies of whales and turtles.

Gen. 6. TUBICINELLA, *Lamarck*.

Shell cylindrical, like a windpipe, narrower at its base. Four large equal shelly plates arranged round the operculum.

Sp. 1. *Lamarckii*.

Cirripedes.

Tubicinella trachealis, *Lamarck.*

Plate LVII.

Gen. 7. CORNULA. *Lamarck.*

Shell subcylindrical, or depressed subconic; base much wider than the apex: lips of operculum very prominent, with two large shelly valves before and one small one on each side of the legs.

Sp. 1. *Diadema*. *Lepas diadema* of authors.

Gen. 8. CHALONIA.

Shell depressed, with its base much wider than its apex; operculum protected by four large equal valves.

Sp. 1. *Savignii*. *Balanus rotundinarius* of authors.

Inhabits turtles.

Family II. BALANIDII.

Operculum testaceous, compressed, bivalve. Base of shell flat or concave.

A. *Base cup-shaped or infundibuliform.*Gen. 9. PRAGOMA, *Savigny MSS.*

Shell undivided. Valves of the operculum bipartite. Base infundibuliform.

The base of the shells of this genus is imbedded in the harder species of coral.

Sp. 1. *Cancellata*. Shell with elevated radiating ribs; interstices cancellated; cancelli and ribs frosted.

Plate LVII. represents two attached to coral, one reversed, and three figures of the operculum; the first complete, the second of one valve, the third of one of the valves separated.

The locality of this species is unknown. J.-C. Savigny sent us another species, which he discovered in the Red Sea; and we have observed a third in the collection of Mr Sowerby.

Gen. 10. CREUSIA.

Shell quadripartite; parts equal. Valves of the operculum unipartite. Base infundibuliform.

This genus is likewise parasitical, and is found attached to coral, in which its base is imbedded.

Sp. 1. *Spinulosa*. Upper parts of the shell with radiating elevated ribs; ribs spinulose; space between the parts of the shell without ribs.

Plate LVII.

Gen. 11. ACASTA.

Shell sexpartite; two parts small, four large. Valves of the operculum bipartite. Base cup-shaped and separate.

The *Acasta* inhabit different sorts of sponge, in which they are found imbedded. We have observed several species in collections, but believe that two only have been described by authors, viz. *Lepas spongites*, *Poli*, tab. vi. fig. 3—6. and

Sp. 2. *Montagui* — *Lepas spongiosa*, *Montagu Test. Brit. Suppl.* page 2. Plate LVII. natural size magnified, and with the operculum magnified.

B. *Base of the form of the substance to which it adheres.*

Gen. 12. BALANUS of authors.

Shell sexpartite; two parts small and four large. Valves of the operculum bipartite.

Sp. 1. *Blainvillii*. Shell rugose, towards the opening striated deeply. Operculum transversely striated; ridges produced into teeth on the anterior margin. Plate LVII.

This species is very common on the coast of Devonshire, adhering to rocks.

Gen. 13. CONIA.

Shell quadripartite, parts equal. Valves of the operculum bipartite.

Sp. 1. *Porosa*.*Balanus porosus* of authors.Gen. 14. CLISIA, *Savigny MSS.*

Shell quadripartite. Valves of the operculum undivided.

Sp. 1. *Striata*.*Balanus striatus*. *Penn. Brit. Zool.* tab. 38. f. 7.

Inhabits the coast of Great Britain, being found attached to marine plants, crustacea, and testaceous mollusca. (v.)

CLACKMANNANSHIRE, one of the counties of Scotland, situated between 56° 5' and 56° 14' north latitude, and between 3° 33' and 3° 56' west longitude from Greenwich, is bounded on the south and south-west, by the river Forth, which separates it from Stirlingshire, by Fifeshire on the south-east, and in every other quarter by Perthshire. It is the smallest county in Scotland, being little more than eight miles long, and, at a medium, six miles and a half broad; thus extending over 52 square miles, or 33,280 acres. But its value is much greater than in the ratio of its extent. About three-fourths of its surface are under cultivation, a greater proportion, with the exception of East Lothian, than that of any other county in Scotland; and it abounds in the useful minerals, which have long been wrought upon a very extensive scale.

Between the Ochill-hills, which form the northern boundary of this district, and the rich alluvial tracts on the banks of the Forth, which winds along in a very irregular line on its opposite extremity, there is a considerable variety of surface. An elevated ridge rises on the west, and, running through the middle of the county, spreads itself gradually till it reaches the eastern boundary, skirting the alluvial or carse lands on the south, and the vale of Doon on the north. And still farther to the north, the Ochill-hills, the highest of which, Bencloch, in the parish of Tillicoultry, rises nearly 2500 feet above the level of the sea, form a very picturesque landscape, having their generally verdant surface broken by bold projecting rocks, and deeply indented ravines, the beds of many a pellucid stream; with coppice and thriving plantations occasionally interspersed. These hills protect the lower grounds from the piercing winds that blow from the north and north-east, and give Clackmannanshire some advantage, in regard to climate, over the adjoining counties.

The only streams worth notice, which traverse this county, are the Doon and the Black Doon, or, as they are often called, the North Doon and South Doon. The Doon rises in the county of Perth, and, descending with impetuosity from the Ochills, where its course is to the east, makes a very acute turn towards the west, and, proceeding placidly in that direction through the pleasant vale already mentioned, falls into the Forth at the village of Cambus. Exclusive of its windings, the course of this river is more than 26 miles, though the distance in a direct line from its source to its entrance does not exceed six miles. It has long been re-

Cirripedes

Clackmannanshire.

Clackmannanshire

markable for the deep and dark chasms which it has worn in the rocks, through which it flows in the earlier part of its course, and in which it is in some places hardly visible. The *Devil's Mill*, so called from the supposed resemblance of the sound of the water to that of machinery; the *Rumbling Bridge*, a very narrow and unguarded pass across a chasm 90 feet deep; and the *Cauldron Lynn*, where the water is perpetually agitated in the immense cauldron-like excavations which it has formed in the rock, have been frequently visited by the lovers of natural scenery. Though this river is liable to be suddenly swelled by rains, and frequently descends in torrents overflowing its banks, it is in general of no great depth, but it is said might be rendered navigable for small vessels at a moderate expence, to the effect of bringing 10,000 acres of coal within reach of water carriage.

The Black Doan has its source in the county of Fife, flows westward in a direction nearly parallel to the Doan, and falls into the Forth near Clackmannan. This river is extensively employed in driving mills and coal engines, its whole course being over coal strata. In a dry season, it is an inconsiderable stream, the greater part of its waters being then collected into reservoirs for the supply of machinery.

The Forth is navigable as far as it forms the boundary of this county. Ships of 500 tons burden come up as far as Alloa. Its windings or *links*, as they are called, are very remarkable. The distance from the quay of Alloa to that of Stirling, measured in the middle of the stream, is 17 miles, and to the bridge of Stirling it is 19½, whereas the distance by land from the latter place to Alloa, does not exceed seven miles. A little above Alloa there are three islets in the river, the largest containing more than 70 acres. A remarkable ledge of rock stretches across the Forth below the two smaller islets, which obstructs the passage of vessels of more than 60 tons burden, and where it is fordable at low water of spring tides. The breadth at this place being only about 500 yards, it was long since proposed to throw a bridge over it, the expence of which was estimated at £70,000. Mr Rennie, the celebrated engineer, has made a survey with a view to a bridge at the Alloa ferry, which he declared to be practicable at an expence of £150,000; a work which it has been very lately attempted to set a going by means of a loan from Government, but with little probability of success. The estuary of the Forth, for several miles above and below Clackmannan, exhibits a singular phenomenon in its tides, which rise there from 16 to 22 feet. During neap tides in good weather, and sometimes also during spring tides, if the weather be uncommonly fine, after the water has flowed for three hours, it retires in an hour and a half, nearly as far as the line from which it had begun to flow, returning immediately and, in an hour and a half more, reaching the same height it had attained before. This flux and reflux takes place both in the flood and ebb tides, so that double the usual number of tides occur in this part of the river. In very boisterous weather, however, these *leaky tides*, as they are called by sailors, are not re-

gular, the water then only rising without any perceptible current, as if two tides were acting against each other.

The soils of the arable land of Clackmannanshire are in general productive and well cultivated; though the greater part of the elevated range which is interposed between the carse lands on the Forth, and the vale of Doan at the bottom of the Ochill hills on the north, consists of inferior soils, often incumbent on an impervious clay. All the crops commonly raised in Scotland grow luxuriantly on either side of this tract, which also contains within itself a considerable proportion of valuable soil. From the rental of the Abbey of Cambuskenneth, founded in 1147, it appears, that wheat was cultivated on the links of the Forth, at a very early period, yet it is certain that, forty years ago, fields of this grain were only occasionally to be met with in the county. As a proof how early and well the carse lands near Alloa have been cultivated, it may be mentioned, that more than a century ago, some farms in that quarter paid as much grain and other kinds of produce, as rent, as the present money rent of similar soils would purchase at the average prices of the last twenty-five years. The farms would be thought small in other counties, few of the arable ones exceeding 200 Scotch (250 English) acres; and the far greater number being below 100 acres. The rent of the county was returned to the collector of the property-tax for the year ending April 1811, at £32,047, 12s., so that, after making allowance for what part of the surface is covered by water, or otherwise altogether unproductive, every acre must have paid at least 20s. upon an average of all soils and situations. At the same time, the rent of the houses was stated at £2,827, 5s. The old valuation, by which land-tax and county-rates are apportioned, is £26,482, 10s. 10d. Scots, or £2,206, 17s. 7d. Sterling, of which somewhat more than a third belongs to estates held under entail. The first effective thrashing machine in Scotland was constructed at Kilbagie, in the parish of Clackmannan, in 1787, by Mr George Meikle, the son of its celebrated inventor; and the last one, it is believed, at which old Meikle himself worked, is on the estate of Mr Erskine of Mar, near Alloa, and still in complete repair. One of the greatest disadvantages which the agriculture of this district labours under, is the want of limestone, of which, however, very large quantities are procured by the farmers from the quarries near Dunbar, and afterwards calcined in the county, where coal is always plentiful and cheap. Limestone that has already undergone this process is also imported to a considerable extent from the Earl of Elgin's works in Fife.

This small county is rich in minerals. Silver, copper, lead, iron-ore (*hematites*), cobalt, and arsenic, have all been discovered in the Ochill mountains, between Airthry and Dollar; but, after having been wrought for a time with little success, the labour has been discontinued. The operations, however, were not conducted upon an extensive scale; in no instance did the miners penetrate below the level of the plain from which the Ochills rise; and it is still believed that these hills abound in valuable metallic veins, ready

to reward more skilful and enterprising adventurers. Ironstone is wrought to a considerable extent for the Devon iron-works in the parish of Clackmannan. It is found either in strata, or in detached oblate balls, imbedded in the schist, and yields from 25 to 30 per cent. of iron.

Millstones.

The Abbey Craig, near Stirling, a great mass of greenstone rock, crystallized in the internal structure, and rudely columnar in its external appearance, deserves to be particularly noticed, in this general view of Clackmannanshire, for its having afforded a very useful substitute, in the manufacture of flour, for the French bur-stones, which it was so difficult to procure during the late war. This discovery was made by a miller of the name of James Brownhill, then employed at the Alloa mills. Several hundreds of these millstones are now working both in England and Scotland, and are found to be in some respects superior to the burs. The *Society for the Encouragement of Arts* in London presented this ingenious person with 100 guineas for his discovery, after they had received the most satisfactory proofs of its great importance.

Coal has been wrought for 200 years in this county. The present annual output may be estimated at 130,000 tons, of which a great part is shipped for Leith, Dunbar, and Tay water, and the remainder consumed by manufactories near the collieries, and by private families. In the scale of working, the collieries stand thus: 1. Alloa. 2. Sauchy. 3. Clackmannan. 4. Dollar. 5. Kennet. 6. Tilli-coultry; besides partial workings in every parish in the county, Logie excepted. It is all either cubical or slate coal (both are often found in the same bed), of an open burning quality; no smithy or caking coal having yet been discovered. The thinnest seam which has been wrought is 27-inches thick; and in a depth of 105 fathoms, there are nine seams of more than this thickness. The strata which compose the coal-field are varieties of sandstone, argillaceous schistus, fire-clay, and argillaceous ironstone. Limestone is found among the lowest veins of the coal strata. Organic remains of shell-fish and plants abound in them. Of the latter, many are of a kind now found only in the equatorial regions. Carbonic acid gas, termed choak-damp, is the most abundant of the noxious vapours found in the coal mines of this field. Hydrogen gas, or inflammable air, was never known here till lately, and it is still in small quantity. The great coal field of Scotland, which passes in a diagonal line from the mouths of the Forth and Tay to the Irish sea, is bounded by the Ochill hills. No coal has been found to the north of them, excepting at Brora, in the county of Sutherland.

Machinery.

Machinery for drawing water from the mines was constructed and much improved in this county, before the invention of the steam-engine. The Alloa colliery is drained by an overshot water wheel, 30 feet diameter, which lifts the water from the depth of 300 feet. The Sauchy collieries are drained by powerful steam engines; that employed by the Devon Company is capable of raising 1,000,000 gallons of water in twenty-four hours from the depth of 280 feet. At the Alloa colliery there is an improved

cast-iron railway of about 2½ miles in length, upon which a horse takes down eight waggons with as many tons of coals. The general price paid for working great coal is from 2s. to 3s. per ton; and the selling price on the hill 6s. 8d., which is said to yield but a very small return to the coal-master.

Clackmannanshire.

At the Alloa colliery, the workmen have for a Collier's great number of years had a court composed of Court. five of their own number, appointed annually by the proprietor of the works. By this court all differences amongst themselves are settled. The highest fine exacted is half a guinea, and all the fines go into a general fund for the support of the poor.

Under the head of manufactures, the distilleries of this county form by far the most prominent and considerable branch. In this small district there are no fewer than six large distilleries, of which Kilbagie and Kennetpans are the most extensive. These two paid to Government an excise duty greater than the land-tax of Scotland: the former alone, no less, at one time, than about half a million Sterling. Previous to 1788, the quantity of grain annually consumed at Kilbagie exceeded 60,000 bolls (45,000 quarters); and 7000 cattle and 2000 swine were fattened upon the grains and dreg. The saving in the stock of food for man, effected by the stoppage of the distilleries, is therefore much less considerable than has been imagined: an acre of barley used in distillation yielding nearly as much animal food as an acre of middling pasture. It is understood that cattle may be fattened in a complete manner, in the proportion of two, of 50 stone avoirdupois each, for every gallon of a still when working from grain; affording the means, at the same time, of enriching the soil for future crops, by the abundance and good quality of the manure they produce.

The other manufactures of Clackmannanshire, Iron-works. though numerous, are not conducted upon so very extensive a scale. At the Devon iron-works, already noticed, about 60 tons of pig iron are prepared weekly, only a small part of which is used by the foundery at these works. In the parish of Dollar, on the banks of the Doan, a bleachfield was established in 1787, of which the water and the machinery are excellent. The cloth bleached here consists chiefly of the fine table-linen manufactured at Dunfermline. There is a very complete set of corn mills at Alloa, and mills for various purposes in several quarters of the county. To the west of the ferry at Alloa, a glass-work for making bottles has been erected; and, in the neighbourhood, a tile and brick work, and a tannery.

The Port of Alloa is well situated for commerce, Commerce. and has a substantial well built quay, and, a little above the harbour, a dry dock, capable of receiving vessels of large burden; the depth of the water at spring tides being 16 feet, and the width of the gates 34½. There is a custom-house here, which comprehends within its precincts the Creeks of Stirling, Kincardine, and Clackmannan pow, at which 120 vessels are registered, carrying 9000 tons, and navigated by 476 men. There are cleared outwards annually, on an average, from 900 to 1000 vessels, carrying 50,000 tons, and employing about

Clackmannanshire.

2500 seamen. The principal exports are coals, pig-iron, and British spirits, sometimes to the extent of nearly a million of gallons, the greater part of which is carried to the English market. The annual average of the import cargoes is from 400 to 500, consisting, for the most part, of grain for the distilleries, of which a great proportion is barley from the county of Norfolk; or of sugar from Leith, Glasgow, Greenock, London, and Liverpool, when the distilleries work from that article.* Timber, iron, and other commodities, are occasionally imported from the Baltic. The establishment of packets betwixt Alloa and Leith is likely to prove of much benefit to this district from the low rates at which goods are transported. A most convenient and expeditious conveyance for passengers, by means of steam-boats, has been recently introduced, with great success, between Newhaven and Alloa, and other places on the Forth.

Packets.

Steam-boats.

Antiquities

Among the antiquities of this county may be mentioned the ruins of Castle Campbell, originally called Castle Gloom, in a singularly wild and almost inaccessible situation, within a recess of the mountains, above the village of Dollar. The period of its erection and its early history are unknown. It became the property of the Argyle family in 1465, from whom it derived its present name, and was the ordinary residence of Archibald Earl of Argyle at the time of the Reformation. In this strong hold John Knox found a temporary retreat. In 1644 it was burned by Montrose, and since that time has been suffered to remain in ruin. The tower of Alloa, built prior to the year 1300, the residence of the Erskines, Earls of Mar, and now belonging to the representative of that no-

ble family, is in good preservation. The walls are eleven feet in thickness, and the highest turret is eighty-nine feet from the ground. The tower of Clackmannan was long the seat of the chief of the Bruces, after the failure of the male line. There is a charter, dated 9th December 1359, quoted by Douglas, in which David II. grants to Sir Robert Bruce (whom he there styles his dearly beloved relation) the castle and manor of Clackmannan, with divers other lands within the county. Since the death of Henry Bruce of Clackmannan, in 1772, leaving no male representative, it has been made a question whether the Earl of Elgin or Bruce of Kennet be now the chief of that royal race.

Clackmannanshire.

Clackmannanshire sends a member to Parliament alternately with the county of Kinross. It contains only four parishes, viz. Clackmannan, Alloa, Doilar, and Tillicoultry, together with about a third part of the parish of Logie: the village of Cambuskenneth, in the parish of Stirling, also forms a part of this county. There is no royal burgh in it. Clackmannan, which gives its name to the county, the only town in it besides Alloa, deserves to be noticed rather for the beauty of its situation than for the elegance of its buildings, or the industry of its inhabitants. There is no assessment here for the poor, except in the parish of Logie, of which the proportion paid by this county a few years ago was from L. 13 to L. 14. The total number of poor in 1812 was 193, who received L. 673, or nearly L. 3, 10s. each, from interest of money, collections at the church doors, and other voluntary offerings. The population of Clackmannanshire in 1800 and 1811 is exhibited in the following abstracts.

Clare
County.
Situation.

CLARE, a county in the south-west of Ireland, is bounded on the north and north-east by the county of Galway, by the Shannon, which separates it, on the east, from Tipperary, and, on the south, from Limerick and Kerry, and on the west by the Atlantic Ocean. It is of a triangular form; its west and south sides meeting in a point at Cape Lean or Loop Head, on its south-west extremity, and the bounding line between it and Galway forming the base. It extends about 42 miles from north to south, and 66 from east to west; but, from the inequality of its breadth, contains little more than 1200 square miles, equal to 476,200 Irish, or 771,365 English acres, of which not quite a half is deemed productive land, and is chargeable with cess. Along all the coast from Galway Bay on the north, to the mouth of the Shannon on the south, a distance of 40 miles, there is no safe harbour for large vessels. On the banks of the Shannon and the Fergus, there are tracts of rich low ground, called *corcass*, of various breadths and irregular in form; and much of the higher lands, though rocky, yield excellent herbage for sheep; but a large proportion of the whole county consists of moors, mountains, and bogs, with more than a hundred lakes interspersed, and without the shelter of natural wood, and rarely of plantations, the extent of which is very limited. The climate, though moist, is not unfavourable to health and longevity; fevers, which sometimes prevail to a great extent here, being occasioned chiefly by the dampness of the houses, and inattention to domestic and personal cleanliness.

Rivers.

The only rivers of any note in this county, or connected with it, are the Shannon and Fergus. The former, after almost dividing Ireland from north to south, enters the Atlantic Ocean between this county and Kerry, where it is about five miles broad. Vessels of 400 tons burden come up this river to the quay of Limerick, from whence the navigation is continued by a canal to Dublin. The Fergus, which has its source within the county, after passing through a number of lakes, and receiving the waters of several smaller streams, pursues its course through the town of Ennis, and, forming a beautiful estuary of picturesque islands, unites with the Shannon at about ten miles distance. It is navigable for vessels of 200 tons burden for about eight miles, and after heavy rains rises so considerably and rapidly, that it frequently overflows large tracts of meadows on its banks. *Turloughs*, called in other places *Loughans*, are numerous. These are accumulations of water, either forced under ground from a higher level, or surface-water from higher grounds, that have no outlet, and must remain until evaporated in summer. Although the water remains on them for several months, yet, on its subsiding, fine grass springs up and supports large herds of cattle and flocks of sheep during the dry season. Mineral waters are found in many places, to several of which, owing perhaps to their sanative virtues, superstition has assigned the name of holy wells.

Minerals.

Clare County is said not to be deficient in mineral productions, but these have not hitherto been turned to much account. Coal has been found, but the working of it is not prosecuted, and ironstone, of which there are strong indications, has never

been sought for. Limestone abounds, and detached rocks of it are sometimes surrounded by bogs, where it may be calcined at a small expence. There are quarries of slate nearly equal to the Welsh, worked to some extent at Killaloe and Broadford. Very fine black marble has been found near Ennis; lead ore in various places; also manganese, copper, beautiful fluor spar, and antimony.

Clare
County.

The agriculture of this county would seem to have made little progress of late, some of the most recent writers on the statistics of Ireland still referring to Mr Arthur Young's *Tour*, written about 10 years ago, as if that work contained a faithful picture of the present state of the county. Clare, however, is not an exception to the advances that have been so generally made towards a more perfect system during that long period; though, in this important art, in which the far greater number of the people are employed, it is certainly far behind several counties on both sides of the Channel. All the different species of grain are cultivated here with considerable success. Rape and flax, the former chiefly for its seed, and the latter for home manufacture, are sown to a moderate extent. Potatoes occupy a part of every farm, and their culture is conducted with more care and judgment than that of any other crop, though at a greater expence of time and labour than would be thought necessary in most other places. In regard to the kinds of crops cultivated, the greatest defect is in what are called green crops, corn being, with potatoes, the chief and almost the only objects of attention to the arable farmer; and turnips and cultivated herbage being either grown on a very small scale, or, as is the case throughout the greater part of the county, altogether disregarded or unknown. The corn crops thus necessarily follow each other until the soil is exhausted; and where extra manure, such as sea-weed and sea-sand, both of which are used as manure with good effect, cannot be procured, it must be left in an unproductive state for several years afterwards. Potatoes are in most cases planted upon land that has been prepared by burning, and the same crop is sometimes taken for two years more without manure; in the fourth year, wheat follows, and then repeated crops of oats as long as they will replace the cost of seed and labour. The implements in common use are generally rudely constructed, and imperfect as well as expensive in their operation. In many parts, even where the soil is light and dry, the plough is drawn by four horses abreast, with traces of rope and collars of straw. But from the roughness of the surface, the poverty of the tenantry, and the minute division of farm lands, the spade is much more extensively employed than the plough, over all the arable land of this county.

The pastures of the *corcasses* or low grounds on the rivers Shannon and Fergus, are equal to the fattening of the largest oxen. This rich tract extends from Paradise to Limerick, about 20 miles, and is computed to contain about 20,000 acres of a deep dark-coloured soil over a bluish or black clay, or moory substratum, producing, owing to the indolence of its occupiers, along with the most valuable herbage, a great quantity of rushes and other useless weeds. The rent of this land for grazing was seven

Re-

Clare County.	ral years ago as high as L. 5 per acre, equal to about L. 3, 2s. per English acre, and for meadow, in many instances, much more. These meadows are said to produce at the rate of more than four tons of hay the English acre. The cattle of this county are almost all long horned, good milkers, and very hardy. The sheep have been greatly improved in shape by crosses with Leicester rams, but there is a general complaint that the quality of the native wool has been deteriorated. A vast number of mules are bred here; asses are very generally employed by the poorer classes; but little attention is paid to the breed of horses, which has degenerated.	is not uncommon for a man to exclude the access of the water through a rent in the hide with his foot, when such an accident happens at sea; he frequently applies his wig and other parts of his dress to the same purpose; and in this dangerous situation remains, with the utmost indifference, exposed to the violent surf that generally beats on this shore. Oysters, and crabs and lobsters, are caught in considerable quantity. The salmon fishery of the Shannon is very valuable; a few of these fish are found in all the rivers that communicate with the sea. Eels, which abound in every rivulet, form another material article of consumpt, but the mischief occasioned by their weirs is probably greater than their value. Other kinds of fish are caught at particular seasons, but only in small quantities.	County.
Live Stock.			
Farms.	The size of farms varies greatly. Those under tillage are from one or two acres to fifty, but of the latter size there are few. Grazing farms extend from 100 to 800 acres, several of which, and sometimes in distant situations, are held by one individual. Frequently several persons join in the occupation of an arable farm, and have about ten acres each. The general term of leases, from proprietors, is for three lives or 31 years; sometimes, but not often, three lives and 31 years; 21 years or one life, and 21 years and a life. The tenure of under tenants is variable, and often arbitrary.	The population of Clare county is stated, conjecturally, at about 120,000; the number of houses being 18,050. Ennis, the county-town, and the only town of any size, may contain 9,000 inhabitants. The houses of the great body of the people are built of stone, without cement,—in the mountains and bogs, often of sods; and heath, fern, and sometimes potatoe haulm, are used instead of straw for thatch. On the damp and dirty floor, their beds of straw or hay are often shared with their pig and dog. So fond are they of the smoke, which they say keeps them warm, that, in cottages erected by proprietors with chimneys, they have been known to prevent its escape by placing a flat stone or turf on the top of the funnel. Yet out of these huts issue the sinewy arms and the daring spuits that contribute so much to the glory of our fleets and armies. Peat or turf, which abounds in every part of the country, is the only fuel, a labourer will cut as much of it in two days, as will serve his family for a year, and his wife and children save it. Potatoes, with or without milk, fish occasionally, and a few vegetables, compose their diet. The quantity of potatoes consumed by a family of six in a week, appears very great, being usually about 22 stones, or at the rate of 8½ lb. daily, for each; but the pig and the other domestic animals also partake of the meal, and strangers never meet with a refusal. The men are clothed in frize, and the women in flannel dyed a bad red, both articles the manufacture of the family; though when the latter go to chapel or market, they frequently dress in dimity and other cotton fabrics, which they procure in barter for the surplus of their domestic manufactures. The men frequently in summer, and the women almost always, go without shoes and stockings, and the latter are so tenacious of this custom, that it is with difficulty they can be persuaded to wear them when taken into gentlemen's houses. The wages of common labour are from 8d. to 10d. a-day. Fairs and markets are almost the only places where drunkenness prevails, but it commonly ends in a few broken heads, and sometimes a little swearing before a magistrate. Matters, however, are generally accommodated by the friends of the parties. Schools abound in this county, and in summer they are numerous attended, yet with a few exceptions, they are far from being under good management.	Population
Leases			Houses
Orchards	Clare was formerly noted for its orchards, and for cyder of a very fine quality made from the celebrated cackagee apple, which is still found near the small town called Six Mile Bridge. "An acre of trees," says Mr Young, "yields from four to ten hogsheads per annum, average six, and what is very uncommon in the cyder counties of England, yield a crop every year." It does not appear, from the latest accounts, that any considerable quantity of this cyder is now produced here, though what there is seems to maintain its former character, and is held in great estimation.		Food.
Manufactures.	Manufactures are yet in their infancy. All the linen made in the county is used for home consumption, the greater part of it being coarse and low priced. Some judgment may be formed of the extent of this branch, when it is known that there are but three small bleachfields in the county. Coarse woollens called frize, and worsted stockings, coatings at one establishment, broad cloth at another, and blankets at a third, with some serges, comprise all the products of the woollen manufacture to be found here, none of them upon an extensive scale, and affording very little for exportation. A considerable number of coarse hats are made near Skar; they are dyed with alder bark and twigs, and logwood, but principally the first. A great deal of kelp is made on the extensive shores of this county, but in so careless a manner that the value is considerably less than that of the kelp of Scotland, and brings only about two-thirds of its price per ton.		Clothes
Fishery	The fishery on this coast has not been prosecuted to any extent, though it is said that no part of Ireland is so well situated for carrying on a lucrative fishery. In the herring season there may be about 200 boats employed, but there is a want of proper regulations, and of authority to enforce such as there are. These boats are, in general, such as have been used from the remotest period of history, wicker-work, covered with hides. It	Clare county was anciently called Thomond or Tuadmuin, that is, North-Munster. The origin of	Schools.

its present name is disputed. In the year 1365, this district was made a county, and added to the province of Connaught, but was restored to Munster in 1602. It forms part of the united diocese of Killaloe and Kilfenora, is divided into nine baronies and seventy-nine parishes, having only according to Dutton's survey, eighteen resident clergymen, and contains, besides Ennis already mentioned, the towns or rather villages of Killaloe, Kilrush, Innistymon, Six-Mile-Bridge, Corrofin, Kilfenora, Skariff, and Miltowa. The people are represented in the Parliament of the united kingdom by two members for the county, and one for the borough of Ennis. The proportion between the Protestants and Catholics has not been ascertained; but it is well understood that the latter are by far the most numerous. Except in the more remote situations of the county, the English language is pretty generally understood, though the Irish is spoken almost exclusively by the country people. It is not, however, used in the schools, nor by the children of the higher classes, and the English tongue must therefore soon become universal.

Remains of ancient buildings, both religious and military, abound in this county. No less than 113

castles are enumerated, besides many *raths* or circular entrenchments of earth or stone, called Danish forts, and *cromlechs* supposed to be sepulchral monuments, one of which, at Balgannor, has a single stone about 40 feet long, and 10 feet broad. Scattery, a beautiful island in the mouth of the Shannon, is rich in these works of an early age. There is a tower on it 120 feet high, an useful land-mark to mariners, the ruins of a castle and several churches, and a monastery said to have been founded by St Patrick in the fifth century. This island is still remarkable for the resort of pilgrims on certain festivals. At a place called *Taunple na Spanigg*, "the burial-place of the Spaniards," a part of the Spanish Armada was wrecked. There was an oak table on board one of the ships, of curious workmanship, which is yet in high preservation in the hall of Dromoland house, the seat of Sir Edward O'Brien.—See Young's *Tour in Ireland*, Vol. I.—Beaufort's *Memoir*, 1792.—Dutton's *Statistical Survey of Clare*, 1808.—Newenham's *View of Ireland*, 1809.—Wakefield's *Statistical and Political Account of Ireland*, 1812.—And, Mason's *Statistical Survey*, of which two volumes only are yet published. Climate.

CLIMATE.

Our theory of climate, which is commonly treated in a very loose manner, would require much elaborate discussion, and a skillful application of the most refined principles in physical science. But, to form a solid basis for the superstructure, there are still wanted accurate and numerous meteorological facts, which can only be obtained from the diffusion of nice instruments, joined to the zeal of careful observers. We had, besides, expected before this time to have been able to embody the results of some new and delicate researches into the constitution and properties of our atmosphere. Those experiments, however, are not quite completed and brought to their ultimate degree of precision. We must, therefore, content ourselves for the present with tracing the great outlines, reserving the full exposition of the subject to the article METEOROLOGY.

ANCIENT V. The word *Climate*, or *κλίμα*, being derived from the verb *κλίνω*, to incline, was applied by the ancients, to signify that obliquity of the sphere with respect to the horizon from which results the inequality of day and night. The great astronomer and geographer Ptolemy, distinguished the surface of our globe from the Equator to the Arctic Circle, into climates or parallel zones, corresponding to the successive increase of a quarter of an hour in the length of midsummer-day. Within the tropics, these zones are nearly of equal breadth; but, in the higher latitudes, they contract so much, that it was deemed enough to reckon them by their doubles, answering consequently to intervals of half-an hour in the extension of the longest day. To compute them is an easy problem in spherical trigonometry. As the sine of the excess of the semidiurnal arc above a quadrant is to the radius, so is the tangent of the obliquity of the ecliptic, or of $23^{\circ} 28'$, to the cotangent of the latitude.

The semidiurnal arcs are assumed to be $91^{\circ} 52\frac{1}{2}'$, $93^{\circ} 15'$, $95^{\circ} 37\frac{1}{2}'$, $97^{\circ} 30'$, &c.; and the following table, extracted from Ptolemy's great work, will give some general idea of the distribution of seasons over the surface of our globe:

Climate, or Parallel.	Latitude.	Length of Midsummer day.	Breadth of Zone.
I.	0 0	12h. 00'	4° 15'
II.	4° 15'	12 15	4 10
III.	8 25	12 30	4 5
IV.	12 30	12 45	3 57
V.	16 27	13 00	3 47
VI.	20 15	13 15	3 38
VII.	23 51	13 30	3 21
VIII.	27 12	13 45	3 10
IX.	30 22	14 00	2 56
X.	33 18	14 15	2 42
XI.	36 00	14 30	2 35
XII.	38 35	14 45	2 21
XIII.	40 56	15 00	2 9
XIV.	43 4	15 15	1 57
XV.	45 1	15 30	1 50
XVI.	46 51	15 45	1 41
XVII.	48 32	16 00	1 32
XVIII.	50 4	16 15	1 36
XIX.	51 40	16 30	1 10
XX.	52 50	16 45	1 40
XXI.	54 30	17 00	1 30
XXII.	55 00	17 15	1 00
XXIII.	56 00	17 30	1 00
XXIV.	57 00	17 45	30
XXV.	58 00	18 00	
XXVI.	59 30	18 30	

Climate.

These numbers are calculated on the supposition that the obliquity of the ecliptic was $23^{\circ} 51' 20''$, to which, according to the theory of Laplace, it must have actually approached in the time of Ptolemy. They seem to be affected by some small errors, especially in the parallels beyond the seventeenth, as the irregular breadth of the zone abundantly shows; but they are, on the whole, more accurate than those given by Varenus.

Ptolemy describes the general appearances which the heavens will present on each parallel, and assigns the corresponding lengths of the shadow of the gnomon at both solstices. He justly maintains, in opposition to the more ancient opinion, that the equatorial region is habitable, since the action of the sun, not continuing long vertical, is there mitigated; but he will not venture to describe the inhabitants, because, no person, he says, having yet penetrated so far south, the reports circulated respecting them appeared to be merely conjectural. He therefore passes over the first parallel to the second.

This second parallel, then, according to Ptolemy, runs through the isle of Taprobana, supposed to be Ceylon, in the latitude of $4^{\circ} 15'$. The third parallel, in the latitude of $8^{\circ} 25'$, traverses the gulf of *Auatus*. The fourth parallel crosses the *Adulitic* gulf, in latitude $12^{\circ} 45'$. The fifth parallel passes through the isle of *Meroc*, in Upper Egypt, at latitude $16^{\circ} 27'$. The sixth parallel runs through the territory of the *Napati*, in latitude $20^{\circ} 15'$. All these climates or parallels, lying below the tropic, the inhabitants are therefore *Amphiscians*, or see the sun pass twice over their heads in the course of the year. The seventh parallel, at the latitude of $23^{\circ} 51'$, and consequently bordering the tropic, runs through *Syené* in Upper Egypt. The eighth parallel, in latitude $27^{\circ} 12'$, traverses *Ptolemais* in the *Thebaid*. The ninth zone, corresponding to a day of 14 hours of length, passes through Lower Egypt, at the latitude of $36^{\circ} 12'$. The tenth parallel, in latitude $39^{\circ} 18'$, runs through the middle of *Phœnicia*. The eleventh parallel, at the 36th degree of latitude, passes through the isle of *Rhodes*. The twelfth parallel, in latitude $38^{\circ} 35'$, crosses *Smyrna*. The thirteenth parallel traverses the *Hellespont*, in latitude $40^{\circ} 56'$. The fourteenth parallel, in latitude $43^{\circ} 4'$, runs through *Marseilles*. The fifteenth parallel passes through the middle of the *Pontic Sea*, in latitude $45^{\circ} 1'$. The sixteenth parallel runs through the sources of the *Ister* or *Danube*, in latitude $46^{\circ} 51'$. The seventeenth parallel, corresponding to a day of 16 hours in length, traverses the mouths of the *Borysthenes*, in latitude $48^{\circ} 32'$. The eighteenth parallel, at the latitude of $50^{\circ} 4'$, crosses the *Palus Mæotis*. The nineteenth parallel passes through the most southern part of Britain, in latitude $51^{\circ} 40'$. The twentieth parallel crosses the mouths of the *Rhine*, in latitude $54^{\circ} 50'$. The twenty-first parallel passes through the mouths of the *Tanaïs*, in latitude $54^{\circ} 30'$. The twenty-second parallel, at the 55th degree of latitude, traverses the country of the *Brigantes*, in Great Britain, that is, the southern and larger portion of this island, reckoning from the Firth of *Forth*. The twenty-third parallel, in the 56th degree of latitude, passes through the middle of Great Britain. The twenty-fourth parallel, at the

latitude of 57° , runs through *Caturactonium* in Great Britain. The twenty-fifth parallel, corresponding to a day of 18 hours long, runs through the southern parts of Little Britain, in latitude 58° . The twenty-sixth parallel, corresponding to a day of $18\frac{1}{2}$ hours in length, traverses the middle of Little Britain, in latitude $59^{\circ} 30'$. It should be observed that the latitudes of the places in our own island are most inaccurately given by Ptolemy, and generally advanced about two or three degrees farther north than their true position. By Little Britain, he meant undoubtedly that part of Scotland which lies on the north side of the Firths of *Forth* and *Clyde*, and forms almost a peninsula.

The high zones become so narrow, that Ptolemy separates the twenty-sixth to an interval of half instead of a quarter of an hour in the length of the day; but he thinks it superfluous to extend this subdivision farther into such remote and inhospitable countries. Resuming the calculation, however, he places the parallel where midsummer day is prolonged to 19 hours in the latitude of 61° , or the north of Little Britain. The parallel of 19 hours would pass through the *Ebudes*, or *Western Isles*, in latitude 62° . The parallel of 20 hours runs through the island of *Thule*, in the latitude of 63° . The parallel of 21 hours would traverse the unknown *Scythian nations*, in latitude $64\frac{1}{2}^{\circ}$. The parallels of 22 and 23 hours would run through the latitudes of $65\frac{1}{2}^{\circ}$ and 66° . He places in latitude $66^{\circ} 8' 40''$ the Arctic Circle itself, where the sun does not set during the whole of midsummer day. Within this circle, the inhabitants are *Periscians*, or have the sun lingering above the horizon during part of the summer, and the shadow of the gnomon successively projected in every direction. In the latitude of 67° , the sun continues almost a whole month above the horizon; in the latitude of $69\frac{1}{2}^{\circ}$, he shines two months; and, in the latitudes of $73\frac{1}{2}^{\circ}$, $78\frac{1}{2}^{\circ}$, and 84° , that luminary displays his presence for three, four, and five months. At the pole itself, the sun appears, during the space of six months, describing circles parallel to the horizon.

CLIMATE, in its modern acceptation, signifies that peculiar condition of the atmosphere in regard to heat and moisture which prevails in any given place. The diversified character which it displays, has been generally referred to the combined operation of several different causes, which are all reducible, however, to these two—distance from the equator,—and height above the level of the sea. Latitude and local elevation form, indeed, the great bases of the law of Climate, and any other modifications have only a partial and very limited influence.

If we dig into the ground, we find the temperature to become gradually more steady, till we reach a depth of perhaps forty or fifty feet, below which it continues unchanged. When this perforation is made during winter, the ground gets sensibly warmer till the limit is attained; but, in summer, on the contrary, it grows always colder, till it has gained the same limit. At a certain depth, therefore, under the surface, the temperature of the ground remains quite permanent. Nor is there any indication whatever of the supposed existence of a central fire,

Climate.

Modern Application of this word

Temperature below the surface of the Earth.

Climate.

since the alleged increase of heat near the bottom of the profoundest excavations is merely accidental, being occasioned by the multitude of burning tapers consumed in conducting the operations of mining. Accordingly, while the air of those confined chambers feels often oppressively warm, the water which flows along the floors seems comparatively cold, or rather preserves the medium heat.

It would be a hasty conclusion, however, to regard this limit of temperature as the natural and absolute heat of our globe. If we dig on the summit of a mountain or any very elevated spot, we shall discover the ground to be considerably colder than in the plain below; or, if we make a similar perforation on the same level, but in a more southern latitude, we shall find greater warmth than before. The heat thus obtained at some moderate depth is hence only the mean result of all the various impressions which the surface of the earth receives from the sun and the atmosphere.

The method employed hitherto for ascertaining the temperature at different depths under ground, consists in digging a hole, and burying a sluggish thermometer for several hours, or the space of a whole night. The celebrated naturalist and accurate observer, Saussure, in the month of October 1785, made an interesting set of observations on the banks of the Arve, near Geneva. By digging downwards on successive days, he reached at last the depth of 31 feet. While the surface of the ground had retained a heat of $60^{\circ}.3$ by Fahrenheit's scale, the temperature of the earth at the depth of 4 feet was $60^{\circ}.8$, at 16 feet 56° , at 21 feet $53^{\circ}.6$, and at 28 feet $51^{\circ}.8$. A thermometer buried 31 feet deep was found, when taken up in summer, to stand at $49^{\circ}.5$, and, when raised in winter, to indicate $52^{\circ}.2$. Notwithstanding this great depth, therefore, it had still felt the vicissitude of the seasons, having varied $2^{\circ}.7$ in the course of the year. The extreme impressions must have taken six months to penetrate to the bulb, since the temperature was lowest in summer and highest in winter.

But this plan of observing is clumsy and imperfect, there not being sufficient time to allow the mass of earth to regain its proper degree of heat, and too much for the instrument to retain its impression unaltered before it can be raised up and observed. In order to throw distinct light on a subject so curious and important, Robert Ferguson, Esq. of Raith, a gentleman whose elegant mind is imbued with the love of science, caused, lately, a series of large mercurial thermometers, with stems of unusual length, to be planted in his spacious garden at Abbotshall, about 50 feet above the level of the sea, and near a mile from the shore of Kirkaldy, in latitude $56^{\circ} 10'$. The main part of each stem having a very narrow bore, had a piece of wider tube joined above it; and to support the internal pressure of the column of mercury, the bulbs were formed of thick cylinders. The instruments, inclosed for protection in wooden cases, were then sunk beside each other to the depths of one, two, four, and eight feet, in a soft gravelly soil, which turns, at four feet below the surface, into quicksand, or a bed of sand and water. These thermometers were carefully observed from time to time by Mr Charles Norval,

the very intelligent gardener at Raith; and we have now before us a register of their variations for nearly three years. It thence appears, that, in this climate and on naked soil, the frost seldom or never penetrates one foot into the ground. The thermometer at that depth fell to 33° of Fahrenheit on the 30th December 1815, and remained at the same point till the 12th February 1816; but, in the ensuing year, it descended no lower than 34° , at which it continued stationary from the 23d December 1816 to 1st January 1817. At the same depth, of one foot, it reached the maximum 58° on the 13th July 1815, but, in the following year, it rose only to 54° , on the 21st July; and, in the year 1817, it mounted to 56° , about the 5th July. This thermometer, in the space of three years, travelled, therefore, over an interval of 25° , the medium being $45\frac{1}{2}$, and attained its highest and lowest points three weeks after the solstice of summer and winter.

The thermometer planted at the depth of two feet, sunk to 36° on the 4th February 1816; but it stood at 38° about the beginning of January 1817. It rose to 56° on the 1st of August 1815; but, in the next year, it reached only 53° , on 24th July; and, in 1817, it again reached 56° , on 10th July. At the depth of two feet, the extreme variation was, therefore, 20° ; and the maxima and minima took place about four or five weeks after either solstice.

The thermometer of four feet depth had sunk to 39° about the 11th February 1816; and was stationary at 40° near the 3d February 1817. It rose to 54° , on the 2d August 1815; and stood at 52° during the greater part of August and September in the years 1816 and 1817. It ranged, therefore, only 15° , the mean being $46\frac{1}{2}$, and the extreme points occurring near two months after either solstice.

The thermometer, whose bulb was planted eight feet deep, descended to 42° on the 16th February 1816, but stood at $42\frac{1}{2}$ on the 11th February 1817. It rose to $51\frac{1}{2}$ on the 12th September 1815, fell to 50° on the 14th September 1816, and mounted again to 51° on the 20th September 1817. This thermometer had, therefore, a range of only $9\frac{1}{2}$, the medium temperature being $46\frac{1}{2}$, and the extremes of heat and cold occurring nearly three months after the solstice of summer and of winter.

These observations are quite satisfactory, and exhibit very clearly the slow progress by which the impressions of heat or cold penetrate into the ground. It will not be far from the truth to estimate the rate of this penetration at an inch every day. The thermometers hence attained their maximum at different periods, though in a tolerably regular succession. The mean temperature of the ground, however, seemed rather to increase with the depth; but this anomaly has evidently proceeded from the coldness of the two last summers, and particularly that of 1816, which occasioned such late harvests and scanty crops. Thus, the thermometer of one foot indicated the medium heat of only $43^{\circ}.8$ during the whole of the year 1816. But it will be satisfactory to exhibit the leading facts in a tabular form. The following are the mean results for each month, only those for December 1817 are supplied from the corresponding month in 1815:

Climate.

Depth to which Frost penetrates.

Climate.

If the thermometers had been sunk considerably deeper, they would, no doubt, have indicated a mean temperature of $47^{\circ}.7$. Such is the permanent temperature of a copious spring which flows at a short distance, and about the same elevation, from the side of a basaltic or greenstone rock. Profuse fountains and deep wells, which are fed by percolation through the crevices of the strata, furnish the surest and easiest mensuration of the temperature of the earth's crust. The body of water which bursts from the caverns of Vaucluse, and forms almost immediately a respectable and translucent river, has been observed not to vary in its temperature, by the tenth part of a degree, through all the seasons of the year. It is, therefore, an object highly important for scientific travellers, to notice the precise heat of springs in favourable situations, as they issue from their rocky beds. Such choice observations would accurately fix the medium temperature of any climate. It is only requisite to exclude the superficial and the thermal springs, which are not difficult to distinguish.

Rule for
Calculating
the Mean
Temperature
of any
Place.

From a comparison of meteorological observations made at distant points on the surface of our globe, the celebrated Astronomer Professor Mayer of Göttingen, was enabled to discover an empirical law which connects most harmoniously the various results. Round the pole, the mean temperature may be assumed at the precise limit of freezing, since the fields of ice accumulated in that forlorn region seem at this present period neither to increase nor diminish. But under the equator the medium heat on the level of the sea is found to be $84\frac{1}{2}^{\circ}$ of Fahrenheit, or 29 centesimal degrees, the division of the thermometric scale which is the best suited to philosophical purposes. At the middle point, or the latitude of 45° , the temperature is likewise the exact mean, or $14\frac{1}{2}^{\circ}$ centigrade. From that centre, the heat diminishes rapidly northwards, and increases with equal rapidity towards the south. Hence the mean temperature of any place, at the level of the sea, is calculated in centesimal degrees, by multiplying the square of the cosine of the latitude into the constant number 29;

or it is found by multiplying the supplemental versed sine of double the latitude into $14\frac{1}{2}^{\circ}$. The variation of temperature for each degree of latitude is hence denoted centesimally, with very great precision, by half the sine of double the latitude; being, in fact, this quantity diminished in the ratio of 58, the double of 29, to 57.3, the length of an arch equal to the radius. From these data, the following table is computed; in which are likewise annexed the corresponding degrees of Fahrenheit's, with the successive differences.

Lat.	Centesimal.	Diff.	Fahrenheit.	Diff.

Little Variation of the Mean Temperature at the Poles and Equator.

It hence appears, that, near the extremities of the quadrant, or towards the pole and the equator, there is scarcely any sensible variation of the mean temperature, and that the whole change within the arctic circle, or between the tropics, amounts only to 8 degrees on Fahrenheit's scale. Very little increase of heat is, therefore, observed in advancing through the torrid zone to the equator; and the intensity of the cold would not be sensibly augmented in penetrating from the arctic circle to the pole. The existence of an open sea towards the extreme north is hence not improbable.

On the other hand, the character of the climate changes rapidly in the temperate zone. Hence likewise the variety of vegetable productions with which those happier regions abound. Such a country as France, for example, stretching from about the 40th to the 50th degree of latitude, and through a difference of five centesimal degrees of mean temperature, yields not only plentiful crops of wheat, barley, and oats, but raises olives, fig-trees, and vines.

The gradation of temperature in different latitudes may be clearly shown by a geometrical diagram. Let the figure below represent a quadrant, 90 the pole, and

50 the latitude of any place; on the radius as an axis and a parameter, describe a parabola, which will consequently pass through the pole; draw the perpendicular 50 B, and the portion of it AB, intercepted within the parabola, will express the mean temperature of the given place at the level of the sea, which in the present case should amount to 12 centesimal degrees.

Since each elementary zone of the sphere is equal to the corresponding belt of a circumscribed cylinder, the whole heat accumulated on its surface must be proportional to the area of the annexed parabola, and, consequently, the mean temperature is two-thirds of what obtains at the equator, and, therefore, $19\frac{1}{2}^{\circ}$ or $66^{\circ} 8'$ on Fahrenheit's scale. Such must be the temperature of the great mass of the earth, if it has derived all its heat from external impressions. But, at the very small depths to which we can ever penetrate, the influence of the immediate vicinity only is felt; nor, in the profoundest mines, has any tendency been yet perceived towards increase of temperature in the higher latitudes, or of decrease in the lower.

These superficial impressions are all produced either directly, or through the intervention of the atmosphere, by the action of the solar rays. It may be calculated from experiment, that the entire and unimpaired light of a vertical sun will communicate one centesimal degree of heat every hour to a sheet of water of a foot in thickness. Consequently, since the surface of a sphere is four times that of its generating circle, such a sheet of water, spread over the

Calculation of the Effect of the Solar Rays.

Climate.

whole of the globe, would receive six rees of heat every day. But the very inferior capacity of the atmosphere for heat, being estimated as equal to that of a body of water about 12 feet in depth, if the aerial mass finally received and retained all the calorific impressions, it would every day have its temperature raised half a degree, and, therefore, augmented to $182\frac{1}{2}^{\circ}$ in the course of a whole year. This annual accession of heat, however, is quickly dispersed by the mobility of the fluid medium, and gradually absorbed into the earth, or more quickly diffused through the waters of the ocean, which, besides, occupy at least three-fourths of the whole surface of our globe. The luminous matter, communicated by the incessant shining of the sun, whether received on the ground, or intercepted in its passage through the air, would hence be capable of communicating one centesimal degree of heat to the body of the earth in the space of 1323 years; a quantity too small, perhaps, to be yet perceived, though its influence may be afterwards detected by very delicate observations.

It is easy to demonstrate, from the laws of optics, that the quantity of light which falls on a horizontal surface must be proportional to the sine of its obliquity. Hence the aggregate light received under the equator at either equinox, is to what would accumulate during twenty-four hours, if maintained at its highest intensity, as the diameter to the circumference of a circle. This daily accession of heat, confined to the mass of atmosphere, would, therefore, in that climate and season, amount to 633 thousand parts of a degree. At the pole itself, during the complete circuit of the sun in midsummer's day, the measure of heat would be about a fourth part greater, or 797 thousand parts; the continued endurance of the sun above the horizon more than compensating for the feebleness of his oblique rays.

In general, the quantity of light received at any place from the sun in the space of one day is denoted by the product of the sine of the semidiurnal arc, or the distance from noon to the time of sun-setting, into the cosines of the latitude and declination, joined to the product of that arc itself into the sines of the latitude and declination; the latter part of the expression being considered as additive or subtractive, according as the declination lies on the same or on the opposite side of the latitude. Hence, at Edinburgh, in the latitude of 56° , the heat collected during one day at the summer solstice is 307 thousand parts, but at the solstice of winter only 166.

If a calculation be instituted for the quantities of heat during the half yearly periods, from the equinox of spring to that of autumn, and from the autumnal equinox again to the vernal, the following table will be formed.

	Summer.	Winter.	Whole Year.
Equator . . .	116°	116°	232°
Tropic . . .	127	87	214
Latitude 45° .	120	42	162
Arctic circle .	102	12	114
Pole	84	00	84

Climate.

The annual accumulation at the latitude of 45° is thus 162° , which differs very little from 158° , the mean between the calorific effects at the equator and at the pole. It may be observed likewise, that the effects vary more slowly at the extremes than near the middle of the quadrant. Thus, from the equator to the tropic, and from the arctic circle to the pole, the differences are 30° and 28° ; but in the narrower intervals, from the tropic to the latitude of 45° , and thence to the arctic circle, the differences are 52° and 48° . The property now stated corresponds with the changes of mean temperature in different latitudes.

If a current of air from the equator, having the ordinary temperature of 29° , were supposed to travel to the pole, from which an equal and contrary current would consequently flow towards the equator, each journey would transport 58 degrees of heat. Between two and three such journies performed every year, would therefore be sufficient to disperse the whole accumulation of 148° . This only requires the existence of a wind advancing northwards at the rate of 46 miles every day. It is not necessary even that the wind should either continue permanent, or blow directly north. The same effect would be produced, if it were to blow indifferently to every point of the compass, and only at the rate of three miles an hour; a supposition which agrees perfectly with actual observation.

The circulation excited in the body of our atmosphere thus prevents the heat shed by the sun on different parts of the earth's surface from an excessive accumulation. In proportion as the equatorial regions grew warmer from the predominance of illumination, the polar wind would rush with more rapidity, till it had tempered the excess. This balance of the accession, and the consequent dispersion, of heat, has probably been long attained, and it now regulates the gradation of climates in successive latitudes. But if air had possessed the capacity for heat which belongs to hydrogen gas, it would have produced a more equable diffusion of temperature, in such that the temperature of the equator could not have become ten degrees warmer than that of the poles. On the contrary, had our atmosphere been less fluid, or less capable of containing heat, the inequality of different climates would have risen to a higher pitch. That variety of temperature which occurs at present on the surface of the globe, was requisite for the developement of the different vegetable tribes which clothe it. The same harmony connects the system of this lower world which irradiates the expanse of the celestial regions.

The equilibrium of temperature preserved over the globe by the circulation of the atmosphere, is not, however, very quickly produced. Hence the remarkable increase of heat which takes place during the summer months in the higher latitudes. But within the arctic circle, another powerful agent of Nature, is constantly tempering the inequality of the seasons. The vast beds of snow or fields of ice which cover the land and the sea in those dreary retreats, absorb, in the act of thawing or passing again to the liquid form, all the surplus heat collected during the continuance of a nightless summer. The rigour of winter, when darkness resumes her tedious reign, is likewise mitigated by the warmth

Climate. evolved as congelation spreads over the watery surface.

Of the light received from the sun, which, by its union with other bodies, constitutes heat, a considerable portion is always detained and absorbed, in its passage through the atmosphere. Even a vertical ray shot through the clearest air, will lose more than the fifth part of its intensity, before it reaches the surface of the earth. In most cases, the loss which light will suffer in the shortest transit through the atmosphere, may be estimated at one-fourth of the whole. But the oblique rays must undergo a much greater absorption. If, from their slanting course, they have to encounter twice the number of aerial particles, their intensity must be reduced to nine-sixteenths or the square of three-fourths; and if they describe triple the vertical tract, only twenty-seven sixty-fourth parts, or the cube of three-fourths, will reach the ground. In general, if the tracts of light follow an arithmetical progression, the diminished force with which it escapes and arrives at the ground, will form a decreasing geometrical one. To determine the train of aerial particles which the oblique rays of the sun must traverse in their passage through the atmosphere, is a nice problem, which requires a skilful application of the integral calculus. Without stopping to engage, at present, in the details of this intricate investigation, it may suffice to remark, that, in general, the length of the tract is nearly in the inverse ratio of the sine of the sun's altitude. But the following table, to every five degrees, is calculated from rigorous formulæ, the length of oblique tract being reduced to the same standard of air uniformly dense. These quantities again are diminished in the ratio of the sine of obliquity, to express the calorific action which those enfeebled and slanting rays finally exert at the surface of the earth.

Sun's Altitude.	Measure of Atmospheric Tract.	Intensity of the Light Transmitted.	Calorific Action at the Surface.

It hence appears that, even when the sky is most serene, only one-half of the sun's light can reach the surface of the earth from an altitude of 25°, or one-

third from that of 15°, and that, if the obliquity of the rays were increased to 5°, no more than the twentieth part of them would actually be transmitted. The annual quantity of light which falls may be computed as equivalent at the equator to an uniform illumination from an altitude of 17° 46'; and, in the mean latitude of 45° and at the pole, the effects are the same as if the rays had respectively the constant obliquities of 13° 2' and 7° 17'. Wherefore, under the most favourable circumstances, of 1000 parts of light transmitted from the sun, only 378 can, at a medium estimate, penetrate to the surface at the equator, 228 in the latitude of 45°, and 110 at the pole of their oblique rays; but the shades received by a given portion of the surface are still less, being only 115, 51, and 14. In cloudy weather, the portion of light that can finally reach the ground will seldom amount to the third of those quantities; and when the sky becomes darkened with accumulated vapours, almost every shining ray is intercepted in its passage.

The light which at last gains the surface being there absorbed and converted into heat, is, in this form, profusely delivered to the ambient air, or more feebly conducted downwards into the body of the earth. But the rays which fall on seas or lakes are not immediately arrested in their course; they penetrate always with diminishing energy, till, at a certain depth, they are no longer visible. This depth depends, without doubt, on the clearness of the medium, though probably not one tenth part of the incident light can advance five fathoms in most translucent water. The surface of the ocean is not, therefore, like that of the land, heated by the direct action of the sun during the day, since his rays are not intercepted at their entrance, but suffered partially to descend into the mass, and to waste their calorific power on a liquid stratum of ten or twelve feet in thickness.

But the surface of deep collections of water is kept always warmer than the ordinary standard of the place, by the operation of another cause, arising from the peculiar constitution of fluids. Although these are capable, like solids, of conducting heat slowly through their mass, yet they transfer it principally in a copious flow by their internal mobility. The heated portions of a fluid being dilated, must continue to float on the surface; while the portions which are cooled, becoming consequently denser, will sink downwards by their superior gravity. Hence the bed of a very deep pool is always excessively cold, since the atmospheric influences are modified in their effects by the laws of statics. The mean temperature of the climate is not communicated by those variable impressions; every change to warmth being spent on the upper stratum, while every transition to cold penetrates to the bottom, which thus experiences all the rigours of winter, without receiving any share of the summer's heat. But, if the beds of profound bodies of water remain perpetually cold, their surface undergoes some variety of temperature, and is generally warmer than the average weekly or monthly heat of the air.

These principles are confirmed by observations made on our own lakes, and strikingly exemplified in

Climate.

Influence of the Sun's Rays upon Seas and Lakes.

Climate.

those of Switzerland, which have a breadth proportioned to the stupendous altitude of their circling mountains. It appears, from the careful observations of Saussure, that the bottoms of those majestic basins, whether situate in the lower plains, or embosomed in the regions of the upper Alps, are almost all of them equally cold, being only a few degrees above the point of congelation. That accurate observer found the temperature of the Lake of Geneva, at the depth of 1000 feet, to be 42° , and could discover no monthly variation under 160 feet from the surface. In the course of July, he examined the Lakes of Thun and Lucerne; the former at the depth of 370, and the latter at that of 640 feet, had both the temperature of 41° , while the superficial waters indicated respectively 64° and $68\frac{1}{2}^{\circ}$, by Fahrenheit's scale. The bottom of the Lago Maggiore, on the Italian side of the Alps, was a little warmer, being 44° at the depth of 360 feet, while the surface was almost as high as 78° . Barlocchi has since found that the Lago Sabatino, near Rome, at the depth of 490 feet, was only $44\frac{1}{2}^{\circ}$, while the thermometer, dipped at the surface, marked 77° .

Through the friendship of Mr James Jardine, Civil Engineer, we are enabled to give the results of his observations on some of the principal Scottish lakes, which, as might be expected from him, were conducted with the most scrupulous accuracy. The instrument which he employed for exploring the temperature at different depths, was free from the ordinary objections; being a register thermometer, let down in a horizontal position, which could acquire the impression in not many seconds, and might be drawn up leisurely, without risk of subsequent alteration. It would appear, that the variable impressions of the seasons do not penetrate more than 15 or 20 fathoms; that, below this depth, an almost uniform coldness prevails. Thus, in the deepest part of Loch Lomond, on the 8th September 1812, the temperature of the surface was $39^{\circ}.3$ of Fahrenheit; at the depth of 15 fathoms $43^{\circ}.7$; at that of 40 fathoms $41^{\circ}.3$; and, from that point, to about 3 feet from the bottom, at 100 fathoms, it decreased only the fifth part of a degree. Again, on the preceding day, the superficial water of Loch Katarine being at $57^{\circ}.3$, the thermometer, let down 10 fathoms, indicated $50^{\circ}.6$; at the depth of 20 fathoms it marked $48^{\circ}.1$; at the depth of 35 fathoms it fell to $41^{\circ}.1$; and on the verge of the bottom, at 80 fathoms, it had only varied to 41° . At the same place, on the 3d September 1814, the heat of the surface was $56^{\circ}.4$; at the depth of 10 fathoms $49^{\circ}.2$; at that of 20 fathoms 44° ; at that of 30 fathoms $41^{\circ}.9$; and at that of 80 fathoms $41^{\circ}.3$.

Hence it is that, even in the northern latitudes, the deep lakes are never, during the hardest winters, completely frozen over. But if the same water be let into a shallow basin, it will, in a rigorous season, be chilled thoroughly, and converted into ice. This may even happen when spread above the surface of salt water, which is always considerably denser. Thus, frost takes no effect on Loch Ness, nor on the river of that name, which, in a rapid course of a few miles, discharges the surplus water into the sea. But in very severe winters, a sheet of ice appears formed along the shore; the impressions of cold being almost

Climate.

wholly expended on the accumulation of fresh water, since the chilled portions of this which continually descend are stopped in their progress by the greater density of the recumbent sea water.

The seas, and the ocean itself obey the same law of the distribution of heat; only the difference of temperature experienced by sounding in the Mediterranean is less conspicuous than in the fresh-water lakes. Saussure found the temperature at the bottom, in the Gulf of Nice and of Genoa, at the depths of 925 and of 1920 feet, was the same, or $55^{\circ}.8$, the heat of the superficial water being about 69° . But the mean temperature, or that of the body of the land on the same parallel of latitude, is 59° . The smallness of the diminution here observed may perhaps be attributed to the effect of evaporation in such hot confined bays, the water at the surface being thus rendered salter, and consequently disposed, by its acquired density, to sink into the colder mass below.

In open seas, and in damper climates, the depression of temperature is greater in the inferior strata. This difference becomes augmented in proportion of the extreme variation of the seasons. Lord Mulgrave, on the 4th September 1773, in the latitude of 65° north, drew up water from the depth of 4100 feet, which he found to have the temperature of 40° , while the thermometer, dipped at the surface, stood, on the 19th June, at 55° . In the latitude of 66° , a register thermometer, let down 4680 feet, marked 26° , while the air was at $48\frac{1}{2}^{\circ}$; and on the 31st August, in the latitude of 69° , while the exterior thermometer indicated $59\frac{1}{2}^{\circ}$, the temperature of the water at the depth of 4040 feet was only 32° . In shallow seas, the two extremes are brought closer together, and therefore a similar difference of temperature now occurs at moderate depths. The water lying on the surface, which, in the vicissitude of the season, comes to be chilled, is not precipitated as before to a fathomless abyss. The increase of cold below is hence considered as an indication of the proximity of banks, if not of the approach to land itself.

A like gradation of temperature is produced by the alternating influence of the seasons in deep and stagnant masses of air. When this active fluid is confined in profound caverns, opening to the sky without being much exposed, and either perpendicular or gently inclined, its lower strata become intensely and permanently cold. The mild air of summer floats motionless at the mouth of the pit; but, in winter, the superior air, cooled many degrees perhaps below the freezing point, and therefore greatly condensed, precipitates itself continually to the bottom.

This fact takes place in most caverns, and in draw-wells which are left uncovered. Saussure found, on the first of July, when the thermometer in the shade stood at 78° of Fahrenheit, that a cave in the Monte Testaceo, a small hill in the vicinity of Rome, formed entirely by the enormous accumulation of broken pottery, had the temperature of 50° ; and two other caves in the same porous mass cooled to 44° . On the 9th July, when the external air was at 61° , the cave of St Marino, at the foot of a sandstone hill, about 2080 feet above the level of the sea, indicated only $44\frac{1}{2}^{\circ}$.

CLIMATE

Climate. which is 8° degrees below the mean temperature of the soil in that situation. In the grotto of Ischia, and in the caves of Cusi and of Chiavenna, the thermometer marked likewise 44° ; but, in the caves of Caprino, on the borders of the Lake of Lugano, it stood at different times of the year at 37° , and at 42° ; and in those of Hergisweil, near Lucerne, the heat of the interior, on the 31st of July, was only 39° .

But this phenomenon is still more striking in certain peculiar circumstances. The famous Swedish mine of Dannemora, which yields the richest iron ore in the world, presents an immense excavation, probably two or three hundred feet in depth. On the occasion of some repairs, which suspended the usual labours, the basin appeared some years since full of water, with huge blocks of ice floating in it.—The silver mine of Kongsberg in Norway has for its main shaft a frightful open cavern, perhaps three hundred feet deep, and thirty feet wide, of which the bottom is covered with perpetual snow.—Hence, likewise, on the sides of Etna and of the mountains in Spain, the collected snows are preserved all the year in caves and crevices of the rocks, from which natural stores the muleteers carry down, during summer, to the villages and the cities of the plain, a material so necessary to comfort in those parched climates.

Absolute quantity of Heat the same at every Elevation.

Such is the disposition induced in a confined column of air; but, in a free atmosphere, the gradation of temperature is exactly reversed, the lower strata being invariably warmer than the upper. This most important fact in meteorology and physical geography was thought sufficiently explained in the infancy of physical science, from the proximity of the heat supposed to be reflected by the surface of the earth. But it were idle to attempt any serious confutation of such crude ideas. The true cause of the cold that prevails in the higher regions of the atmosphere, is undoubtedly the enlarged capacity which air acquires by rarefaction. From the unequal action of the sun's rays, and the vicissitudes of day and night, a quick and perpetual circulation is maintained between the lower and the upper strata; and it is obvious that, for each portion of air which rises from the surface, an equal and corresponding portion must likewise descend. But that which mounts up, acquiring an augmented attraction for heat, has its temperature proportionally diminished; while the correlative mass falling down, carries its share of heat along with it, and again relaxing its attraction, seems to diffuse warmth below. A stratum at any given height in the atmosphere is hence affected both by the passage of air from below and by the return of air from above, the former absorbing a portion of heat and the latter evolving it. But the mean temperature at every elevation is on the whole still permanent, and, consequently, those disturbing causes must be exactly balanced, or the absolute measure of heat is the same at all heights, suffering merely some external modification from the difference of capacity in the several portions of the fluid with which it has combined. That temperature is hence inversely as

the capacity of air having the rarity due to the given altitude. *Climate.*

It only remains, therefore, to discover the capacity of air, or its attraction for heat under successive pressures, or at different degrees of rarity. But this problem requires a very nice investigation, and appears incapable of being resolved by any direct procedure. If the elaborate experiments of Dr Crawford and others on the capacity of air in its ordinary state, gave such erroneous results, what hope could be formed of ascertaining even its minute shadings by any similar plan of operation? Fortunately, independent almost of any theory, a simple method occurs for conducting this research. A delicate thermometer, suspended within the receiver of an air-pump, indicates a decrease of temperature, as the process of rarefaction advances. But, on stopping this operation at any stage, the thermometer will slowly regain its former state. If now, when the equilibrium is restored, the air be suddenly readmitted, the dilated portion which had remained in the receiver, liberates the heat absorbed by it during the progress of rarefaction. The thermometer, accordingly, rises quickly through a certain space, then becomes, for a short while, stationary, and afterwards slowly subsides. But the instrument does evidently not measure the whole of the heat thus evolved, a great part of it being spent in warming up to the same point the internal surface of the receiver. This action, however, is merely superficial, since its effect appears to be momentary. Consequently, the internal surface of the receiver, with that of the plate on which it stands, as penetrated by the sudden impression to a certain very minute depth, forms a constant film of matter, which, as well as the body of air itself, draws its supply from the extricated heat. Under the same receiver, therefore, although the air will not seize the whole of the heat disengaged in the act of admission, it must always retain a proportional share of it. A series of experiments, at successive degrees of rarefaction, must hence discover, if not the absolute, yet the relative, changes of the air's capacity for heat.

To institute this inquiry with the desired success, an excellent and powerful air-pump was used, having a receiver of the very largest dimensions, of an oblong spheroidal form, approaching, however, nearly to the globular, and with a narrow bottom. The apparatus being placed in the middle of a close room, which had a steady temperature, a thermometer with a slender stem, open at top, and a small bulb of extreme sensibility, was fixed in a vertical position, a few inches above the centre of the plate. Having replaced the receiver, and allowed it to stand some time, one-fifth of the air was now extracted from under it; and, after a considerable interval, the cock was suddenly opened, to restore the equilibrium, and the mercury of the thermometer, which had been stationary, mounted up very rapidly 3.0 centesimal degrees, from which point it afterwards slowly descended.

The temperature of the room having been regained, two-fifths of the air in the receiver was then extracted; and, after some lapse of time, the external

Investigation of the increased Capacity of Rarefied Air.

Details of the Experiment.

Climate.

communication being repeated, the thermometer rose instantly 5.3 centesimal degrees. On extracting three-fifths of the internal air, the corresponding ascent of the thermometer, at the restoration of the equilibrium, was 7.0 of those degrees; and, when the contents of the receiver had been rarefied five times, the heat evolved, on the re-admission of the air, amounted to 8.0 degrees. The rate of progressive effect was thus evidently diminishing. On pushing the rarefaction as far as it was really practicable, or till the residual air had become rarefied about 300 times, the change indicated by the thermometer did not reach to more than 8.3.

But, to determine the absolute quantity of heat which is disengaged in the transition of air from a rarer to a denser state, it becomes necessary to ascertain what part of it was consumed on the sides of the receiver. By varying the size of the receiver, and consequently altering the proportion between its surface and its contents, some light may be thrown on this question. Another similar receiver was therefore provided, having half the former dimensions; and with this the same set of experiments was repeated. Its included air being reduced successively to the density of four-fifths, three-fifths, two-fifths, and one-fifth, and then rarefied as much as possible, the thermometer mounted each time through the shorter spaces of 1.8, 3.2, 4.2, 4.8, and finally 5.0 centesimal degrees. These quantities evidently follow the same proportion as the former, of which indeed they are only three-fifths. But the smaller receiver, having, under the fourth part of the surface of the larger, only the eighth part of its contents, exposes comparatively twice the extent of surface. The rise of temperature which its included air exhibits, must consequently be the same as what would have obtained within the larger receiver, if, while its capacity remained the same, its surface had been actually doubled. If we suppose the air to hold one part of the heat, while two parts and four parts are respectively expended on the insides of the receivers, the results would correspond with observation; for the whole quantity evolved, being in both cases the same, the air under the larger receiver would retain one-third, and, under the smaller receiver, only one-fifth; the impressions being thus in the ratio of five to three. The same conclusion may be obtained somewhat differently. If the heat spent on the inside of the large receiver had been spread over twice the surface, it would have raised the temperature only 2.5; but this mounted really to 1°.8, and therefore the difference .3 was the effects of 1°.8, derived from the contained air. Of the heat thus shared between the air and the doubled surface, one part was hence retained, and five communicated. Consequently, to obtain the true results, it is only necessary to multiply the second set of quantities by five, or the first set by three. If no waste, therefore, took place against the inside of the receiver, the heat evolved in the passage of air from the densities of four-fifths, three-fifths, two-fifths, one-fifth, and extreme rarefaction, to its ordinary state, would be 9, 16, 21, 24, and 25 centesimal degrees.

Influences.

It is not difficult to discover the law of this progression. They are obviously formed by the suc-

cessive addition of the odd numbers 9, 7, 5, 3, and 1; and are, consequently, the excesses of the square of 5 above the squares of 4, 3, 2, and 1. Wherefore, if the square of the density be taken from unit, the remainder, multiplied by 25, will express in centesimal degrees, the rise of temperature which accompanies the return of the air to its ordinary state.

The numbers thus obtained, however, do not still express the final results. If the restoration of four parts of the air included under the receiver to their usual density, disengage heat, sufficient to raise the temperature of the whole five parts 9 degrees, its real measure must have been 11½ degrees, or the former augmented in the ratio of 4 to 5. For the same reason, if three-fifths, two-fifths, and one-fifth of the air in the transition of density, evolve portions of heat, which would elevate the temperature of the mass 16, 21, and 24 degrees, the actual quantities are 26½°, 52½°, and 120°, or those numbers multiplied by 5, and divided by 3, 2, and 1.

These conclusions are easily reduced to formula. G. NORDHOLM Conclusion.
Let θ denote the density of the air, and $25(1 - \theta^2)$ will express, in centesimal degrees, the elevation of the thermometer which would follow the readmission of the air, if none of the heat were spent on the inside of the receiver. Consequently, $25\left(\frac{1 - \theta^2}{\theta}\right)$,

or $25\left(\frac{1}{\theta} - \theta\right)$, will exhibit, on the same scale, the

whole quantity of heat evolved in the restoration of density. The last formula is extremely simple, implying that 25, multiplied into the difference between the density of air and its reciprocal, will represent the measure of heat due to the change of condition. This result may be either additive or subtractive; it may express the heat emitted in the condensation of air, or the heat absorbed during its opposite rarefaction.

Thus, the heat extricated from air which has its density doubled is $25^\circ(2 - \frac{1}{2})$, or $37\frac{1}{2}^\circ$; and the same quantity is withdrawn, either when this air recovers its former density, or when air of the ordinary state expands into double its volume. Hence the copious heat extricated by the sudden compression of air. If it were condensed thirty times, the heat discharged would amount to $25\left(30 - \frac{1}{30}\right)$, or 749° , which

Application of the formula.

is more than sufficient for the inflammation of fungous or soft substances. On this principle, are constructed the pneumatic matches lately invented by Mollet of Lyons, which produce their effect by the momentary action of a small syringe.

But, to discover the relative capacity or attraction which air of a given density has for heat, it would be necessary to know the extent of the natural scale, or the position of the absolute zero. The conclusions, however, from different data, are not very constant; yet several experiments appear to fix nearly the point from which the infusion of heat commences at 300 centesimal degrees below congelation. On this supposition, therefore, air which is rarefied thirty

CLIMATE.

Climate.

times has its capacity doubled, the heat contained in it being dilated only fifteen times. For the same reason, air sixty times rarer than ordinary acquires a triple attraction for heat, which, in this union, becomes attenuated only twenty times. But these inferences are merely speculative, and the law of the gradation of temperature in the atmosphere is quite independent of the existence of an absolute term of heat.

The last formula now investigated has been already laid before the public, without any explication, however, or indeed indication, of the process by which it was discovered. The experiments on which it rests were begun many years since, and have been repeated with every precaution. But the mean results only are retained, and, for the sake of simplicity, a few slight modifications have been introduced, to adapt the apparatus to more convenient proportions. Though it was impossible to blow a receiver that should have exactly half the dimensions of another, nothing seemed easier, from the general mode of investigation, than to apply the minute corrections which any small deviations of size or form required. The mixture of obscure and intricate computations has been thus avoided.

Gradation of Effects represented by a Parabola.

The gradation of the effects disclosed by this experimental research, is more easily and clearly traced in geometrical diagrams. Having divided the absciss AF into five equal portions, erect the several perpendiculars EG, DH, CI, BK, and AL, equal respectively to 9, 16, 21, 24, and 25 parts on any scale, and connect the points F, G, H, I, K, and L, by a curve line. It is readily perceived, that the curve now traced must be a parabola, formed on the axis LA. Wherefore, if AF represent the height of the barometric gage of the air-pump, and AD its altitude after a partial exhaustion, the parallel DH will express the rise of the included thermometer on the re-admission of the air which had been extracted. The axis AL itself denotes the extreme effect, or what would take place if the rarefaction were pushed to the utmost. While the mercurial column, therefore, descends by equal intervals to E, D, C, B, and approximates to A, the elevation of the thermometer through the spaces EG, DH, CI, BK, and nearly AL, advances at first uniformly, and afterwards continually more slowly, till it becomes stationary.

Difference of Temperature produced by the change of the Air's density

But the parallels to the axis of a parabola, do not express the whole of the heat disengaged by the attenuated air during the resumption of its density. The line DH, for instance, marks only the rise of temperature communicated to the entire mass AF, by the heat evolved from the portion AD, and to represent the true measure of this heat, it must, therefore, be increased in the ratio of AD to AF. Hence,

from the point A, and through the extremities of the parallels EG, DH, CI, and BK, draw the oblique lines AG, AH, AI, and AK, to meet the extended perpendicular EO, the intercepted segments of parabolic tangents FM, FN, FO, and FP, (if this last were completed,) will exhibit the real portions of heat liberated from any of the corresponding densities AE, AD, AC, AB.

Climate.

Let the part AL of the axis be taken equal to the parameter, and the ordinate AF must likewise be equal to it: Draw the vertical tangent LQ meeting the parallel DH in Q, join the oblique line AD, and produce it to meet the perpendicular in R. From the property of the curve, QH : AD :: AD : AF; but from the mutual relation of the diverging lines AN, AR, and the parallels DQ and FR, AD · AF ::

AH · AN :: QH : NR, whence QH · NR :: QH · AD, and, therefore, NR is equal to AD. Consequently FN, which expresses the whole evolution of heat corresponding to the density AD, is equal to the difference between AD and FR. But since AD : AF :: DQ or AF : FR, the line FR is the reciprocal of AD, the parameter AF being considered as unit. The measure of heat evolved, or the parabolic tangent FN is, therefore, as before expressed, by the difference of the density of the air and its reciprocal.

The same result may be represented geometrically in another way. Let LIG be a rectangular hyperbola referred to its asymptotes AE and AF, the axis being AO: If the perpendicular IC, or the ab-

Climate.

science AC express the ordinary density of the air, and the ordinate DH, or any other density, the intercepted segment HN, or the difference between DH and its reciprocal AD or DN, will exhibit the additional force of heat required for its constitution. On the contrary, if the air acquires the higher density BK, the quantity of heat which it must evolve

Difference of
Temperature exhibit-
ed.

in its transition will be represented by KP. In the figure here annexed, the air is presumed to have its density reduced to the half in one case, and doubled in the other, the quantities of heat, HN and KP, which are evolved and absorbed, being then equal and opposite.

Since the absolute quantity of heat contained in every part of any vertical column of the atmosphere has been shown to remain unchanged, these diagrams must likewise represent the diminution of temperature in the higher strata, corresponding to the decreased density of the air at different elevations. The same formula will determine the measure and gradation of this effect. Reckoning the density of the air at the surface of the earth unit, the difference between the density at any given altitude and its reciprocal, being multiplied by 25, will express the mean diminution of temperature in centesimal degrees; or if 45 be employed as the multiplier, the product will exhibit the same result in degrees of Fahrenheit's scale.

This very simple deduction, from theory, is amply confirmed by numerous and extensive observations. But a few leading facts will perhaps be deemed sufficient for exemplification.

Examples of
the applica-
tion of the
Formula:

According to Lælius, the same barometer, which, at Goslar, an ancient town seated in the bosom of the Hartz Forest, stands at 29,500 inches, would fall to 26,444 on the top of the Brocken, in that Mining District. This gives .896 for the density of the air on the summit, the reciproc. of which is 1.116; but $1.116 - .896 = .22$, and $.22 \times 25 = 5.5$, the calculated difference of temperatures. The actual difference is very nearly the same, being only 5.2; as we had once an opportunity ourselves of observing, having found the temperature of a copious spring at Goslar to be 8. centesimal degrees, while that of the noted Hecken-Brunnen, or Witch-Well, on the summit of the Brocken, was only 2.8.

Climate.

Saussure, whose accuracy always inspires confidence, found that, while at his villa of Conche, near Geneva, the barometer stood at 28,800, another similar instrument fell to 25,165, on the top of the mountain of Nant Bourant. The diminished density of the air at this elevation was, therefore, .890; the difference between which and its reciprocal 1.123 being multiplied by 25, gives 5.82. But a thermometer, buried a whole night at two feet deep, in that lofty station, marked only 12.75; while it indicated 6.25 more, or 19°, a few days afterwards, when sunk to the same depth at Conche. The discrepancy here is thus less half a degree.

On the top of a higher mountain, the Chapicu, To the Tem-
the same observer found the ground, at a depth of perature of
two feet, to be colder by 6.44 than at Conche. But the Ground
the corresponding density of the air and its reciprocal
were 872 and 1.147; consequently, $25^\circ \times .275 = 6.87$.

While the barometer at Conche stood at 28,500 inches, the mercurial column was only 19,836 inches on the summit of Mont Cervin, a still loftier mountain. The density of the air at this elevation was therefore .696; which being taken from its reciprocal 1.437, leaves 741 to be multiplied by 25, indicating 18.52 as the diminution of temperature. The actual medium difference ascertained from corresponding thermometrical observations, made at depths in the ground, from one to three feet, on the top of Mont Cervin and at Conche, was 18.25, almost exactly the same.

Such is the nice agreement on the whole, between theory and observation, with regard to the decrease of the mean temperature in the higher regions of the atmosphere. This gradation of cold varies, however, to a certain extent with the seasons. Since the heat derived from the sun is chiefly accumulated at the surface of the earth, the changes of temperature which take place through the year in the elevated strata of our atmosphere, must evidently be less than what are experienced below. The lofty tracts of air, remote from the primary scene of action, preserve nearly an equable temperature, and scarcely feel the extreme heat of summer or winter's frost. In ascending the atmosphere, the decrease of warmth is hence more rapid in the fine season, and more slow in the darkened period of the year. In many places, it will not be far from the truth, perhaps, to assume 30° for the multiplier during the summer months, and only 20° during those of winter.

Thus, General Roy, a diligent and experienced observer, found, in the month of August, the air on the top of Sprydon was, in the course of a whole day, at an average 7.2 centesimal degrees colder than on Carnarvon Quay. But the difference between the density at that elevation, and its reciprocal, or between .878 and 1.139 being only .261, would require nearly 28 for the multiplier.

In the early part of September, the same observer noticed the centesimal thermometer to stand 10 degrees lower on the top of Ben Lawers than at Weem, the relative density of the air at that height being .808. The difference from its reciprocal is .284,

CLIMATE.

which would hence require to be multiplied by 25 to give the actual diminution of temperature.

Again, Saussure found, on his visit to Mont Blanc, the air on its summit to be 31 centesimal degrees colder than at Geneva. The relative density was .592, which being taken from its reciprocal 1.689, leaves 1.097; consequently, the multiplier required is 28.

This ingenious philosopher passed several days encamped on the Col du Geant, where he found, from the mean of eighty-five observations, the temperature of the air to be only $4^{\circ}.54$, or $20^{\circ}.3$ colder than at Geneva. But the relative density of that elevated stratum and its reciprocal were .704 and 1.420; the difference of which, or .716, would require to be multiplied by $28\frac{1}{2}$, to indicate the diminished temperature.

The observations made on the decreased temperature of the higher regions of the atmosphere by the ascension of balloons, appear generally to indicate rather a slow rate of diminution. But it should be recollected that those daring aerial flights have seldom been performed except in the fine season of the year. Besides, the car, the balloon, and its cordage, will not immediately acquire the temperature of the elevated strata, but continue for a considerable time to diffuse a sensible portion of heat. A memorable example, however, is entirely conformable to the general principle. Charles, the first who ascended the atmosphere by means of a balloon filled with hydrogen gas, found, on the 1st of December 1783, the thermometer depressed 11 centesimal degrees at the greatest elevation, the column of the barometer having sunk from 29.24 to 20.05 inches. This would require a multiplier less than 20.

Diminution
of Tempera-
ture in the
higher Ele-
vations.

In ascending through equal heights, the density of the atmosphere, as derived from the incumbent pressure, diminishes in a continued proportion. This density is hence represented by the ordinates of a logarithmic curve, of which the absciss denotes the altitude above the surface. The cold which prevails in the upper strata would no doubt modify the dilatation of the air; but, since it follows nearly the same progression, it cannot materially affect the general results. In the figure annexed, the vertical spaces expressing the elevations of one, two, three, and four English miles; the horizontal lines 1D, 2F, 3H, 4K, represent the corresponding mean temperature in the temperate latitudes. But, from the nature of the logarithmic curve, if it were supposed to be continued in like manner below the surface, the horizontal lines at the same equal distances would be the reciprocals of the former. Let this extension of the curve be, therefore, folded back and placed over its first portion, rising from oA, and the difference between the horizontal lines, or the distance between the two branches of the curve, as, from the point A, they constantly spread from each other, will exhibit the diminution of temperature corresponding to the elevation. These branches of the curve at first diverge at the same angle; but the wider branch afterwards spreads with a larger sweep, and their mutual distance slowly increases.

This gradual increasing progression, which marks the diminution of temperature in ascending the atmo-

sphere, is still more apparent from another property of the logarithmic curve. The difference between any two ordinates is constantly proportional to the intercepted area. Consequently, the successive diminution of temperature corresponding to the elevations of one, two, three, or four miles, are expressed by the areas ABDC, CDK, EFHG, and GHKI. But, since the component spaces 0C, 1E, 2G, and 3I, augment evidently faster than 0D, 1F, 2H, and 3K, diminish, the decrements of heat encountered in ascending the atmosphere must, on the whole, increase. It is farther evident, that, if those spaces were reduced to extremely narrow belts, they might be considered as proportional merely to their several lengths; and hence the momentary decrements, or the rate of the diminution of temperature at the heights of one, two, three, and four miles are expressed by the transverse lines CD, EF, GH, and IK. If a calculation be instituted for the temperate climates, while the mean temperature at the level of the sea decreases one centesimal degree during an ascent of 540 feet above the surface, it suffers a similar diminution in 529 feet at the altitude of a mile; but at two, three, four, and five miles of elevation, the same difference will obtain, at the contracting intervals of 498, 454, 401, and 346 feet. Should Fahrenheit's scale be preferred, those numbers multiplied by five, and divided by nine, will give respectively 300, 295, 277, 252, 223, and 192, for the ascents due to a decrement of one degree at the surface, and at the heights of one, two, three, four, and five miles.

Hence the altitude of any place above the surface of the ocean may be nearly ascertained from an observation of its mean temperature. In the milder climates, it will be sufficiently accurate, in moderate elevations, to reckon an ascent of 540 feet for each centesimal degree, or 100 yards for each degree on Fahrenheit's scale, of diminished temperature. Thus, the Black Spring, a copious perennial source which bursts forth on the ridge of the Pentland Hills, in the vicinity of Edinburgh, is found to indicate only $7^{\circ}.2$ centesimal degrees, or $1^{\circ}.6$ less than the medium due to that parallel. But $1^{\circ}.6$ multiplied by 540 gives 868 feet; which differs by a few feet only from the altitude, as determined by actual levelling.

Climate.

Again, we have obtained the temperature of a perpetual and descending spring in the meadow below the well-known margin of the branching lake of the Fontainebleau, to be only 10 centesimal degrees, or 1° below the standard temperature of that latitude. This gives 8.1×540 , or 1890 feet for the elevation of the central valley of Switzerland above the level of the sea.

As a final example, we may cite an observation made in Upper India by Dr Francis Buchanan, who found a spring at Chitlong, in the Lesser Valley of Nepal, to indicate the temperature of 14.7 centesimal degrees; which is $8^{\circ}.1$ below that of the standard of its parallel, or $27^{\circ}, 38'$. Wherefore, 8.1×540 , 4374 feet, is the elevation of that valley.

When the altitude above the sea is very considerable, however, a multiplier somewhat decreasing from 540 must be taken. But it is easy to show, that the same result very nearly will be obtained, by applying a small correction. If the product of 540 into the diminution of temperature, be again multiplied by the square of this difference in centesimal degrees, and then divided by the constant number 15000, the quotient will express the quantity to be subtracted. Thus, in the last example, the square of 8.1 or 65.61 multiplied into 4374 makes 286978, and this divided again by 15000 gives 19, to be deducted from 4374, leaving 4355 for the corrected altitude.

This correction, therefore, amounts only to $33\frac{1}{2}$ feet at the elevation of one mile, but for two, three, four, and five miles, it would rise to 266, 904, 2128, and 3350 feet. Though it augments thus rapidly, it may in ordinary cases be totally disregarded, and the allowance of one degree by Fahrenheit's scale for every hundred yards of ascent, is a rule of most easy recollection.

That the decrements of heat, corresponding to equal ascents in the atmosphere, are not uniform, however, but augment gradually with an accelerating progression, is confirmed by the appeal to actual observation. Thus, in proceeding from Geneva to the Vale of Chamouni, through an elevation of 2094 feet, Saussure found the temperature of the air to decrease only $3\frac{1}{2}$ centesimal degrees, or at the rate of one degree in the rise of 644 feet. Between Chamouni and the Col du Geant, an interval of 7940 feet, the diminution of temperature was 17° , being a degree for each 465 feet of ascent. Again, the summit of Mont Blanc, though only 4400 feet higher than the Col du Geant, was $10^{\circ}.8$ colder, which gives a degree for every rise of 407 feet. The acceleration of cold is here very perceptible, but the gradation from Geneva to Chamouni was unusually slow, owing to the position of this sequestered spot, where the action of the sun-beams, in summer, being sheltered from the influence of dispersing winds, accumulates above the standard. Near the level of the sea, the ascent, corresponding to the decrement of a centesimal degree, very seldom exceeds 600 feet.

Since, in ascending from the surface, the temperature constantly diminishes, there must, in every latitude, exist a certain limit of elevation at which the air will attain the term of congelation. The mountains, likewise, which rear their heads above

that boundary, are covered with eternal snow. In the higher regions of the atmosphere, especially within the tropics, the temperature varies but little throughout the whole year. Hence, in those brilliant climates, the line of perpetual congelation is strongly and distinctly marked. But, in countries remote from the equator, the boundary of frost rises after the heat of summer, and the influence of winter prevails,—thus varying its position over a belt of some considerable breadth.

The height of the limit of perpetual congelation for any latitude, is easily determined from the principles already established. Let t denote the mean temperature in centesimal degrees at the surface of the ocean, and x the density of the upper atmosphere at the line, where the reign of frost begins. It is

evident from the formula, that $\left(\frac{1}{x} - x\right) 25 = t$,

whence $x^2 + .04 tx = 1$, and this quadratic equation being solved, gives $x = \sqrt{1 + .0004 t^2} - .02 t$.

From the density of the air thus found, the corresponding altitude is discovered by the application of logarithms, as in the barometrical measurements. Hence the following table is computed.

Latitude	Height of Curve of Congelation. English Feet.	Latitude	Height of Curve of Congelation. English Feet.

This table, though calculated from theoretical data, will be found to coincide with actual observation. It suggests a variety of important results; and the position of the snowy boundary may direct the intelligent traveller to estimate the elevation of any country. Thus, Ben Nevis, the highest mountain in Scotland, is generally seen covered with snow through the whole year, except during two or three weeks in the month of July. Its summit, therefore, does not reach the limit of congelation, which, at the latitude of 57° , has an altitude of 4334 feet. Accordingly, the height of that mountain is only 4380 feet. Again, we learn from the relations of travellers, that, though perpetual snow covers the stupendous ridge of the Himalaya mountains in Upper India, it descends but a short way along their sides, and leaves, for the *ghauts* or passages below, a grassy plain. But the boundary of congelation traverses the parallel of 30° at the altitude of 11,484 feet, and consequently that towering range may rise probably 4000 or 5000 feet higher, and thus surpass the elevation of Mont Blanc. The pretended altitudes of 23,000 or even 27,000 feet, so recently assigned to those mountains, are hence utterly incredible.

The gradation of altitude which marks the snowy boundary in different latitudes, is most clearly perceived from the inspection of a diagram. Thus, if

Represented by a Curve.

the horizontal line represent the distance of the pole from the equator, divided into 90° , and each vertical line corresponding to the latitude denote the height of the limit of perpetual congelation in English miles, the extremities of these perpendiculars being connected, will form a curve of contrary flexure, of which the one half is nearly the reverse of the other. This curve, therefore, bends slowly at first from the equator; most rapidly about the middle latitudes, but again slants near the surface to the pole.

The ordinates of this curve of congelation, or the altitudes of the limit of eternal frost, might also be found, with sufficient precision, from the corrected gradation of cold, if the primary multiplier were in each parallel of latitude adapted to the mean temperature. In the high latitudes, the correction to be applied is small, but it becomes very considerable within the tropics. Thus, in the middle latitude of 45° , it is only 110 feet; but, under the equator, it amounts to 877 feet. But, except in this extreme case, the altitude of the snowy boundary will, on the whole, differ very little from the product of the mean temperature by 540. That line must, therefore, approximate to a coincidence with the curve formed by referring the series of temperatures to the successive latitudes. Let the tangent O 90 be applied equal to the semicircumference O A 29 of a circle, and

every intermediate point B be determined, by making any parallel 10 A B equal to the intercepted arc A 29. If the absciss then represent the meridian extending from the equator to the pole, the several ordinates will express the corresponding mean temperatures at the level of the sea. The reason of this construction is easily perceived; for the arc O A of the generating circle being equal to the complement of the corresponding latitude, its chord is equal to the cosine of this latitude, which belongs to a circle having twice the diameter of the former; but the ordinate from B, or the perpendicular segment O 10, is proportional to the square of the chord O A and consequently to the square of the cosine of the latitude.

The curve now constructed is what has been called the *Companion of the Cycloid*. In fact, it differs from the cycloid only by the defect of the generat-

Climate.

ing circle. If each parallel AB were extended as far beyond B as 10 A, the cycloid would be traced. This deficient cycloid has obviously the same aspect as the curve of perpetual congelation. It is only less flattened towards the equator, where the correction of altitude chiefly operates. A close inspection, however, is requisite to distinguish their difference.

The companion of the cycloid, or curve of temperatures, might also be formed, by unrolling half the convex surface of a cylindrical wedge or *ungula*. The curve, already delineated, was only the expansion of the annexed figure.

If the semicircumference of the base of the cylinder were divided into 90 equal parts, to denote the successive latitudes from the equator to the pole, the perpendicular lines terminating in the oblique section, would express the

corresponding mean temperatures. These lines, again, might be easily measured by parallels of temperature or arcs of circles, dividing the altitude of the wedge into 29 equal parts, and running parallel to the plane of its base. If the whole wedge or *ungula* were taken, the combination of vertical lines and of horizontal arcs, would exhibit all the gradations of mean temperature, in its progress and subsequent decline from pole to pole. It is easy to perceive, that, on this plan, an elegant instrument could be constructed, equally calculated for illustration and practical use.

Origin of
Glaciers.

The curve of perpetual congelation must evidently rise higher during the tide of summer, and again descend in the winter months, thus oscillating between certain limits of elevation. The intervening belt is narrow under the equator; but it enlarges to a very considerable extent in the higher latitudes. On the breadth of this zone, where frost holds a doubtful reign, depends the formation of *glaciers*, along the flanks of the snowy mountains. The fields of snow, which are alternately melted and congealed, become at last changed by this process into solid ice, often grouped and fashioned by such irregular action into the most fantastic shapes. In its native seat, this icy belt acquires continual additions to its height, till the accumulating pressure at last tears the mass from its base, and precipitates its dissevered fragments to a lower level. In its new position, below the inferior boundary of congelation, the enormous pile suffers,

on the whole, a very gradual thaw, which is sometimes protracted for several centuries. Meanwhile, in the higher magazine, another icy belt is again slowly collecting, which will in due time repeat the succession, and maintain the eternal circle of production and decay.

Climate.

Within the tropics, the zone of undecided frost is so very narrow, that scarcely any trace of a glacier has been ever observed. But as that zone enlarges in the higher latitudes, the appearance of vast glaciers constitutes a very striking feature in the aspect of the lofty mountains. They occur frequently along the sides of the Pyrennees; but they are still more conspicuous in the recesses of the central chain of the Swiss Alps. Glaciers are likewise seen as far north as the verge of the Arctic Circle. Along the western shore of Norway, and the coast of Lapland, stretching onwards to the promontory of the North Cape, huge masses of columnar ice descend from the cliffs, or against the precipitous sides of the mountains, almost to the surface of the ocean.

Through the whole train of investigation now pursued, the warmth which vivifies our globe has been viewed as flowing from the fountain of the Sun. The easiest mode of conceiving the subject is to consider the Heat which permeates all bodies, and unites with them in various proportions, as merely the subtle fluid of Light, in a state of combination. When forcibly discharged or suddenly elicited from any substance, it again resumes its radiant splendour. Such changes are exhibited in the phenomena of Electricity, and in many of the operations of Chemistry. But the production of Light is not less striking in the ordinary business of life. The glowing spark struck from flint, and the consuming fire, which even the rudest tribes had learned to excite by the rapid friction of two pieces of dry wood, were by the ancient philosophers regarded as only detached portions of the divine and celestial flame which illumines the empyreal vault. The same notion was embraced by the poets, and gives sublimity to their finest odes. HEAVENLY LIGHT, INVISIBLE LIGHT, and the LIGHT OF LIFE,* are lofty and refined expressions, which gleam through the mystic hymn of Orpheus.

Heat only
Light in a
Latent
Form.

Those poetical images which have descended to our own times, were hence founded on a close observation of nature. Modern philosophy need not disdain to adopt them, and has only to expand and reduce to precision the original conceptions. If any body be exposed to the sun's incident rays, it will experience a rise of temperature exactly proportioned to the quantity of light intercepted or absorbed. When those rays are either concentrated or attenuated, the effect produced by their detention is proportionally augmented or diminished. The calorific action is occasioned solely by that portion of the light which remains united to the opposing substance. The rays which are either transmitted or reflected, leave no trace of their energy. Neither a very

Climate. bright reflecting surface, nor a fine pellicid medium, is sensibly heated on being exposed even to a meridian sun. But since reflection and transmission cannot be perfect, a certain calorific effect, however small, and varied by circumstances, is always the result. A polished surface of silver may absorb from the tenth to the fifth part of the perpendicular rays; and we have seen that the thin body of atmosphere itself will detain one-fourth part of the vertical light shot down through it, and one half of the beams that slant at an inclination of 25° . The absorption of light in its passage through water is proportionally greater; the perpendicular rays lose half their force by a descent of 17 feet in that medium; become reduced to one-fourth by traversing a path of 34 feet, which corresponds to the mass of an atmosphere. It hence follows, that only the hundred thousandth part of the vertical rays can penetrate below 47 fathoms. But this faint remnant is scarcely equal to the glimmer of the closing twilight. The depths of the ocean are never visited, therefore, by the cheering influence of the great luminary of day.

The rise of temperature produced by the same measure of the absorption of light, is in different substances inversely as their capacity or attraction for heat. Thus, if two very thin glass balls of the same diameter, and coated with China ink, be filled, the one with water and the other with mercury, and exposed to the sun, the latter will mark an accession of five degrees of heat, while the former will indicate only two. Or, if two equal and similar pieces of glass and lead were both of them blackened and presented to the incident solar rays, the lead will acquire a higher temperature than the glass, in the ratio of 12 to 7.

This theory agrees, therefore, in all its bearings, exactly with observation. But facts have been alleged, of a contrary tendency; and some ingenious, yet incorrect experiments, performed by a celebrated astronomer, appear to have, for several years, deceived the public into a belief, that, besides the ordinary mixture of coloured rays emanating from the sun, there is emitted also a cluster of invisible and less refrangible rays, which excite or constitute heat.

Invisible
Rays of
Heat.

As if such an hypothesis were not already sufficiently complex, it was afterwards assumed, that there exists likewise another series of dark rays, more refrangible than usual, whose office it is merely to attract oxygen from the substances on which they fall. But a closer examination of the circumstances have proved, that, in forming these opinions, philosophers have proceeded to generalize too fast. If, while the sky is perfectly clear, which seldom happens indeed in this climate, the solar spectrum formed behind a prism be observed by a differential thermometer in a darkened room, the intensity of the heat will be found to augment most rapidly in passing from the one extremity to the other, from the limit of the violet to that of the red. When a prism of flint-glass was used, we found that the spectrum being divided into four equal spaces, the effects indicated by the thermometer, and corresponding to the range of the violet, the green, the yellow, and the red, were as the square numbers 1, 4, 8, and 16. If the spectrum were formed by another refracting medium, as the intermediate coloured spaces would alter their proportions, so likewise would the calorific action vary. But, in every case, the violet and the red rays which occupy the extremes, must differ very widely in their relative energies. Without the spectrum, however, and beyond the absolute limit of illumination, no sort of action whatever is betrayed. * The distinct effects produced by the extreme coloured spaces may possibly depend on the peculiar qualities of the several rays; but, perhaps, proceed from the character of the diluted or concentrated energy which they display. The violet, or blue, rays will probably hasten the process of darkening a solution of the nitrate of silver; yet have we found, that white light, attenuated to a certain degree, has likewise a power to accelerate this change. It is probable that the collected beams only retard the effect, by exciting heat, which may dispose the oxygen to adhere more strongly to its substratum. In like manner, the intense action of the red rays on the bulb of a thermometer may proceed more from their condensation than from some exclusive quality which they possess. What is the nature of that peculiar constitution which fits a ray of light to excite in the organ of

No Action
whatever be-
yond the Li-
mit of the
Spectrum.

* It may be worth while to state here a very simple, yet decisive experiment, which we have repeated more than once. If a circle of black paper, ten inches in diameter, be pasted over the middle of a burning glass of the diameter of one foot, it will leave, around the margin of the lens, a sort of circular prism, which bends the coloured rays into a hollow double cone, whose intermediate apex occupies the focus. On directing the lens, thus partly shaded, to a bright sun, in a clear sky, a card held perpendicular to the beam, and drawn either forwards or backwards from the focus, will exhibit a narrow coloured ring, opening with intense brilliancy. Between the focus and the lens, the red rays will mark the outer edge of the vivid ring; but beyond that limit, they will cross over and tint the inside. In either case, it was easy to mark their extreme boundary. To examine the graduating calorific action of this condensed spectrum, a broad and flat piece of black sealing wax, having the gloss removed from its surface by a file, and a thin slip of white paper laid across it, was then held in the cone of light two or three inches before the focus, and in the space of a few seconds a very narrow ring, shading inwards however, was distinctly impressed in the wax, the roughened surface being melted and left hollow and glossy, at the exact limit of the red on the outside, and smoothing slightly away on the inside. Beyond the apex of the double cone of light, a similar glazed narrow ring was imprinted, softening from the inside. In both cases, the circular impression on the wax corresponded exactly with the trace of the red rays,—an interval of the fiftieth part of an inch being easily distinguishable.

Climate.

vision any peculiar sensation of colour, it seems impossible to decide. Perhaps the whole distinction consists in the difference of the celerity with which it moves. The peculiar energy of any coloured pencil of light may depend chiefly, if not entirely, on its density. From the violet to the red, the successive tints of the spectrum rise with augmented force. The blue rays appear feeble, the green cause a milder impression, the yellow and the orange begin to glow with intensity, and the red dazzles the eye. The language of painters, being grounded on nice observation, marks appositely the gradation of strength. Blue is by them termed a cold colour, green a soft colour, yellow a rich colour, and red a warm colour.

Photometer.

For measuring the intensity, or at least the calorific action of light, no instrument is so finely adapted by its peculiar delicacy as the *Photometer*, which consists of a *Differential Thermometer*, inclosed in a thin pellucid case, and having one ball made of black and the other of clear glass. It will besides admit of some variety in its form and construction, and may be rendered on the whole very commodious and portable. Yet, owing to a combination of circumstances, this elegant instrument has only been partially and reluctantly admitted; and the philosophic world has still to discharge an act of justice, by receiving it into the favour and distinction which it so well deserves. Some indeed, affecting to display superior sagacity, have taken the trouble to remark that it was only a species of thermometer, and not strictly a photometer, since it measures heat and not light. But what does the thermometer itself, except indicate *expansion*? As heat is measured by the expansion it occasions, so light is determined by the intensity of the heat which, in every supposition, invariably accompanies it. What other mode, after all, could be imagined for detecting the presence of light? How can an unknown quantity be expounded, but in terms of one already known?

Importance of that Instrument.

The photometer is adapted for a variety of important meteorological researches. If such instruments, in the hands of skilful observers, had been dispersed to the remote regions of the globe, we should ere now have obtained a body of precise facts, highly instructive in themselves, and calculated to illustrate the nature of different climates. Meanwhile, we shall endeavour to state the general consequences which may be drawn from even a scanty range of photometrical observations.

The direct and absolute action of the sun's rays on the photometer, at the elevation of 30° , may be reckoned in this climate at 120 millesimal degrees. The effect is produced by the incidence of a pencil of light, which has for its base a circle of the same diameter as the black ball, but modified and regulated in its amount by the subsequent dispersion of the accumulated heat from the whole surface of the sphere, which is four times greater than that of the generating circle. If a thin disc were, therefore, substituted instead of the ball, and presented to the perpendicular rays of the sun, the impression would be doubled or raised to 240° ; or, if the emission of heat from the posterior surface of the disc were prevented, the calorific effect would amount by this accumulation to 480° , or 86 degrees on Fahrenheit's scale.

Such is the rise of temperature which a dark surface of dry mould sloping at an angle of 30° , yet exactly fronting the sun, might acquire under a diaphanous shell of glass, if scarcely any portion of the heat were supposed to be conducted downwards into the mass of the earth. But since the rays of light which traverse the atmosphere under an obliquity of 30° have, in comparison with perpendicular beams, their force diminished in the ratio of 750 to 563; the action of a vertical sun, through a thin capsule of glass, might heat up a dark horizontal surface 118° by Fahrenheit's scale. On removing the glass cover, this effect, in a calm still air, would be reduced about two-thirds or to $75\frac{1}{2}^\circ$.

The colour of the ground or substratum has very little influence in modifying the calorific action of the solar beams. The different shades of brown or gray have almost the same absorbent quality as black itself; yellow and orange begin to cause a partial reflection; but a surface even of pure chalk will not reflect perhaps the fifth part of the incident light. Hence the arid sands of Africa are often heated by a vertical sun to near the point of boiling water; in so much as to scorch the feet of the wretched traveller, and to accumulate warmth sufficient for the slow roasting of an egg. Even within the Arctic Circle, the calorific action of a bright sun, in the height of summer, may exceed 49° . In those dreary regions, accordingly, amidst a dissolving world of ice, the pitch is yet sometimes softened or melted, in the seams of the sides or the decks of ships.

It is obvious that the accumulated effect of the incident rays, must increase in proportion as the conducting power of the medium is diminished. Hence at an elevation of three miles and a half, where the density of the atmosphere is reduced to one-half, the heat communicated would, on this account alone, augment from $75\frac{1}{2}$ to 83 degrees. But the effect would be farther increased, from the smaller absorption of heat in its passage to the surface. Under the equator, the whole accumulated action would, therefore, amount to 96 degrees. All travellers, accordingly, complain of the scorching rays which the sun darts from a dark azure sky on the summits of lofty mountains. Yet the contrast is more striking in the higher latitudes. Thus, in the middle parallel of 45° , the action of the sun at the summer solstice would excite a heat of 69° at the level of the sea, and of 90° at an elevation of three miles and an half; but, at the winter solstice, it would communicate only 17° below and 46° at the altitude assumed. Saussure was accordingly very much struck with the force and brilliancy of the sun-beams on the top of Mont Blanc.

It might easily be computed that, on the supposition of a perfect calm, the surface of the earth, under the equator, will, at the medium of a year, have its temperature raised 12° ; and that, in the latitude of 45° , the mean annual impression would be only 5° . But, of the whole of the light received, the calorific action on a black mould, whether emitted from the sun or shed indirectly by the sky, may be deduced from the indication of the photometer. It is only required to diminish the power of the sun's rays in the ratio of the sine of their obliquity, and to reduce

Climate.

Calorific Action of the Rays in different Circumstances.

Climate. the action of the light reflected from the canopy of clouds to one-half, or what is due to the medium inclination of 30° , then to multiply the sum of these quantities by eight, and divide by three, or to take two-thirds of the quadrupled effect. Thus, suppose, while the sun's altitude is 40° , that the photometer marks 155° , which it very seldom ever reaches in this climate, and that it indicates only 20° , if merely screened from the direct action of the sun. Now, 155° multiplied by the sine of 40° , makes $87^\circ.8$, which is augmented to $97^\circ.8$ by the addition of the half of 20° , and this number again being increased in the ratio of 3 to 8, gives finally 261 millesimal degrees, or 47° on Fahrenheit's scale. When the sun is obscured in clouds, the reflected light, from a dappled sky, will sometimes in summer affect the photometer to the extent of 40° . This corresponds to a heat of 16 degrees of Fahrenheit communicated to the ground. During the fine season, the photometer seldom in cloudy weather indicates less than 15° , which is equivalent to an impression of 6 degrees on the embrowned surface of the earth. While the sun is enveloped in clouds, if the rest of the sky assumes a fine azure hue, the photometer will only mark 10° . But in the gloomy days of winter, the minute portion of light which pierces through the congregated mass of clouds will scarcely affect the photometer 5° , or excite a heat of 2° by Fahrenheit on the ground.

Effect on
the ground
diminished
by Wind :

These augments of temperature are communicated to the ground unimpaired, only in the case, however, of a perfect calm. The agitation of the atmosphere will scatter the heat before it has accumulated. When the wind creeps along the surface of the earth at the rate of eight miles in the hour, it diminishes the calorific action of the light from the sun and from the sky one-half; but if it sweeps with a velocity of 16, 24, or 32 miles in the hour, it will reduce the whole effect successively to the third, the fourth, or the fifth of its standard. The impression made on the ground seldom, therefore, exceeds the third part of the computed measure, and often will not amount to one-fifth.

The simplest and most accurate method of examining the temperature acquired during the day on the surface of the earth, is to employ a differential thermometer of the pendant kind, having about one or two feet in length, and its lower ball surmounted by a small cylindrical cavity supporting the coloured liquor. This instrument being suspended or held in a vertical position, the lower ball resting on the ground, will evidently mark, by its moveable column, the difference between temperature of the surface and that of the ambient air. In this way, we have found, during the summer months in this climate, that the ground was, by Fahrenheit's scale, generally two or three degrees warmer than the air near it in cloudy weather, and perhaps ten or fifteen degrees warmer when the sun shone powerfully upon it. But, under similar circumstances, the effect varies very considerably, according to the nature of the surface. While fresh ploughed land, for instance, indicates an increased temperature of perhaps 8° , a grass plot close beside it will scarcely show a difference of 3° . Nor is this distinction owing to any greater absorption of light by the black mould; the reflexion

from the surface, in both cases, being extremely small. A thin layer of hay, whether spread on the naked soil or on the green turf, will betray the same diminished effect. The fibres of the grass exposing a multiplied surface to the contact of the air, the greater portion of the heat is hence dissipated before accumulation. A corresponding effect has been remarked with respect to the impressions of cold. Thus, in the neighbourhood of Edinburgh, after a long tract of rigorous weather, the frost was found to have penetrated 13 inches into the ground in a ploughed field, but only 8 inches in one piece of pasture ground, and 4 inches in another. But, in some of the streets of that city, the frost had descended even below two feet, so as to begin to affect the water pipes. The greater density and solidity of the pavement had no doubt conducted the frigorific impressions more copiously downwards, while the loose and spongy blades of grass had mostly scattered and wasted those impressions in the open field. This consideration, it is obvious, might lead to very important practical results.

The unequal action of light at the surface of the earth, whether produced by the various obliquity of the sun's rays, the different inclination of the horizon, or the alternating succession of day and night, is attempted, we have seen, by the actual flow of the heated portions of the atmosphere. Between the poles and the equator, a perpetual circulation of air is maintained, which confines the accumulating effects of heat within narrow limits. The prevalence, on the whole, of northerly winds in this hemisphere during summer, and of southerly winds in winter, tends likewise to mitigate the extreme impressions of hot and cold. But a current of warm air excited at first by the presence of the sun, continues to rise from the ground, and occasions the descent, therefore, of an opposite current of cold air, which, as the equilibrium of temperature is not soon restored, may be protracted through a great part of the night. The combined influence of these currents is hence continually exerted, in cooling down the surface of the earth; but their activity being the greatest while the solar beams fall most copiously, the accumulation of heat is checked in little more than an hour after mid-day, while its farther dissipation is prolonged through the whole of the night, sun-rise being generally the moment when the ground is coldest.

Such a concatenated system of aerial currents might hence appear sufficient to explain the gradation and general balance of temperature which prevails on the surface of our globe. An horizontal stream of air must evidently cause the flow of an opposite one, since the action must be the same on every part of the same parallel of latitude. The difference of the temperature of the surface from that of the ambient air will maintain the constant play of an ascending and a descending current. In clear and calm weather, this interchange between the higher and lower strata of the atmosphere will be the most vigorous, owing then to the concentrated impression of the sun-beams. The perpetual commerce maintained in our atmosphere by the medium of these combined horizontal and vertical currents, forms no doubt an essential part of the system which attempers the constitution of this globe. But it is not the only mode by which

Climate. nature seeks to preserve the harmony of her productions; and recent discovery has detected the existence of another auxiliary principle, extremely active, of most rapid and extensive influence, and continually at work, though subject to various modifications. To understand rightly, however, the operation of this principle, it will be necessary to recall the chief facts which have lately been disclosed relative to the PROPAGATION OF HEAT.

Propagation of Heat:

It is well known, that, though partial causes may disturb the equilibrium of temperature among bodies, there is a constant tendency to restore it again. Yet heat still remains in the state of combination, without ever assuming a distinct form. Its balance is, therefore, maintained by a very different process from that which establishes the equilibrium between the several communicating parts of a liquid. The substratum of heat is not passive, nor do the calorific particles themselves merely flow from their redundancy towards another situation where they happen to be deficient. But since the presence of heat is invariably accompanied by corpuscular distention, that portion of the substance which loses it must successively contract, while the portion which gains it will in the same degree expand. The actual transfer of heat through any mass will hence give occasion to a connected series of minute internal contractions and expansions. To consider the subject more fully, we shall suppose the conducting substance to be, 1. A solid; 2. A liquid; and, 3. A gaseous fluid.

1. Through Solids:

1. When the surplus heat is conducted through a solid substance, a sort of alternating vermicular motion is excited along the whole train of communication. If heat were left to the energy of its own repulsion, it would, like light, dart with a speed almost instantaneous. But the time consumed by those interior oscillatory movements retards immensely the rate of transmission. The quickness of the oscillations themselves depends on the elasticity of the conducting substance; but their energy and extent are proportioned to the extreme difference of temperature, and the shortness of the tract, modified essentially by the peculiar nature of the conducting substance. In equal circumstances, glass transmits heat faster than wood, and metal faster than glass. But, even in the same class of conductors, the effects are very different; thus, box delivers the impressions of heat more quickly than cork, and silver conveys them with greater rapidity than platinum.

2. Through Liquids:

2. When the conducting substance is a liquid. The ordinary transmission of heat through a solid, is now greatly augmented from the diffusion occasioned by the mobility of the affected portions of the medium. Below the freezing point, ice will conduct heat through its substance; but, after it has melted into water, a new and powerful agency is brought into play. The liquid particles, as they become successively warmer, acquire a corresponding expansion, and, therefore, rise upwards and spread through the mass, carrying with them and dispersing the heat which they have received. This diffusive buoyancy will depend evidently on the dilatible quality of the liquid. It is greater in alcohol than in water, and in water than in mercury; it is even more active in hot than in cold water. Near the point of congelation, indeed, the joint conducting

power of water is scarcely superior to that of mere ice. The actual flow of a liquid, by whatever cause it is produced, must evidently accelerate the dissipation of heat.

3. When the medium of transmission is a gaseous substance, the heat is partly still conducted through the substance of the communicating mass, as if this were solid, and partly transferred by the streaming of the corpuscles, which come to be successively affected. But a new principle seems here to combine its influence, and the rate of dispersion in æriform media is found to depend chiefly on the nature of the mere heated surface. From a metallic surface, the heat is feebly emitted; but, from a surface of glass, or still better, from one of paper, it is discharged with profusion. If two equal hollow balls of thin bright silver, one of them entirely uncovered, and the other closely enveloped in a coat of cambric, be filled with water slightly warmed, and then suspended in a close room, the former will only lose 11 parts of heat in the same time that the latter will dissipate 20 parts. Of this expenditure, 10 parts from each of the balls is communicated in the ordinary way, by the slow recession of the proximate particles of air, as they come to be successively heated. The rest of the heat, consisting of 1 part from the naked metallic surface, and of 10 from the cased surface, is propagated through the same medium, but with a certain diffusive rapidity, which in a moment shoots its influence to a distance after a mode altogether peculiar to the gaseous fluids.

But those effects are modified by the different proximity of the air to the metallic surface. If the silver ball be covered with the thinnest film of gold-beater's skin, which exceeds not the 3000th part of an inch in thickness, the power of dispersion will be augmented from 1 to 7; if another pellicle be added, there will be a farther increase of this power, from 7 to 9; and so repeatedly growing, till after the application of five coats, when the repellent energy will reach its extreme limit or the measure of 10.

The approximation of the metallic substratum thus evidently diminishes the power of the external pellicle in darting heat. No absolute contact exists in nature; but air must approach to a boundary of pellicle, or cambric, much nearer than to a surface of metal, from which it is always divided by an interval of more than the 500th part of an inch. A vitreous surface has very nearly the same property as one of cambric or paper; from its closer proximity to the recipient medium, it imparts its heat more copiously and energetically than a surface of metal in the same condition.

By what process the several portions of heat thus delivered to the atmosphere, shoot through the fluid mass, it seems more difficult to conceive. They are not transported by the streaming of the heated air, for they suffer no derangement from the most violent agitation of their medium. The air must, therefore, without changing its place, disseminate the impressions it receives of heat, by a sort of undulatory commotion, or a series of alternating pulsations, like those by which it transmits the impulse of sound. The portion of air next the hot surface, suddenly acquiring heat from its vicinity, expands proportionally, and begins the chain of pulsations. In again con-

Performed by Tremulous Pulses:

Climate.

tracting, this aerial shell surrenders its surplus heat to the one immediately before it, now in the act of expansion; and thus the tide of heat rolls onwards, and spreads itself on all sides.

But these pulsations are not propagated with equal intensity in all directions. They are most powerful in the perpendicular to the projecting surface, and diminish as they deviate from that axis in the ratio of the sine of the angle of obliquity.

Nor are the vibratory impressions strictly darted in radiating lines, but each successive pulse, as in the case of sound, presses to gain an equal diffusion. Different obstructions may hence cause the undulations of heat to deflect considerably from their course. Thus, if a cornucopia, formed of pasteboard, present its wide mouth to a fire, a strong heat will, in spite of the gradual inflection of the tube, be concentrated at its narrow end; in the same way, probably, as waves, flowing from an open bay into a narrow harbour, now contracted and bent aside, yet without being reflected, rise into furious billows.

But the same pulsatory system will enable the atmosphere to transmit likewise the impressions of cold. The shell of air adjacent to a frigid surface, becoming suddenly chilled, suffers a corresponding contraction, which must excite a concatenated train of pulsations. This contraction is followed by an immediate expansion, which withdraws a portion of heat from the next succeeding shell, itself now in the act of contracting; and the tide of apparent cold, or rather of deficient heat, shoots forwards with diffusive sweep.

That quality which enables a surface to propel the hot or cold pulses, likewise fits it under other circumstances to receive their impressions. If a vitreous or varnished surface emits heat most copiously, it will also, when opposed to the tide, arrest, with entire efficacy, the affluent wave; and if, on the other hand, a surface of metal sparingly parts with its own heat, it detains only a small share of each warm appulse, and reflects all the rest.

Pyroscope.

Hence the construction of the *Pyroscope*, a delicate and valuable instrument, adapted to measure the warm pulses of air, or the intensity of the heat that darts continually from a fire into a room, which has been vaguely and inaccurately termed *radiant heat*. It is in fact only a modification of the *differential thermometer*, one of the balls being completely gilt with a thick gold or silver leaf. The *pyroscope* being placed at some distance from the fire, the hot pulses are mostly thrown back from the bright metallic surface; but, on the naked glass ball, they produce their full impression. But the same instrument will serve equally to indicate the pulsations excited from a cold surface. Thus, in a warm apartment, the *pyroscope* placed before a mass of snow, a block of ice, or even a pitcher of water from the fountain, will quickly intimate the chilling impressions propagated through the ambient medium. Nor has the brightness of the fire or the glare of the snow any sensible influence to affect the result, for of the small portion of light transmitted, what falls on the diaphanous ball passes almost without obstruction, and what strikes the gilt ball, especially if this be covered with silver leaf, is nearly all reflected.

But the *pyroscope*, in its simple form, is scarcely

Climate.

calculated for making nice observations, when exposed out of doors to the agitation of winds and the effulgence of light. A greater share of this light will generally be detained by the gilt surface than what is absorbed in its passage through the diaphanous ball. On the other hand, all the effects on the instrument will be diminished by the rapidity of the circulation of the air.

The application of the *pyroscope* incontestibly shows, that no pulsation, whether calorific or frigorific, ever takes place, except from a conterminous surface, which is either hotter or colder than the surrounding gaseous medium. If the general equilibrium of temperature be interrupted, such aerial pulses will arise, whether the boundary of excitation be solid or liquid. They are produced feebly from a surface of metal, though evidently stronger from mercury than from silver; but they are projected with most energy from a surface of glass, and still more powerfully from one of varnish, of paper, of ice, and of water.

But since those hot or cold pulses are darted from such various surfaces, and since the softness of the external coat, and its tendency to fluidity, seem vastly to augment their power; may they not likewise be excited from a boundary of air itself? This extension of a great principle in the economy of nature has never yet been surmised; nor can it be readily brought to the test of direct experiment. A body of air, whether hotter or colder than the general medium, it is evident, could not remain for a moment in the same detached situation, but would continue to rise or to fall. In a confined place, however, a stratum of warm air may float incumbent over a mass of colder fluid. The difference of temperature between the conterminous surfaces, would no doubt be constantly diminishing from the slow intermixture and subsequent diffusion of the adjacent portions of the air. This tendency to an equilibrium might be counteracted, by causing either a constant stream of warm air to enter by the edges of the ceiling of the apartment, or one of cold air to flow from the side of the floor. Such would be the most favourable arrangement for performing the experiment. Both the ceiling and the floor would obviously soon acquire the same temperature as the current spreading over them, and could therefore exert no influence whatever in projecting the aerial pulses. If, under such circumstances, those pulses be hence found to exist, they must necessarily proceed from the action excited at the bounding surface which divides the warm from the cold stratum of air.

But an arrangement, less perfect indeed, yet sufficient for ascertaining the main fact, is entirely within our reach. In a close apartment, where a good fire is constantly kept up, the ceiling and the floor may be discovered by the pendant differential thermometer to have exactly the same temperature with its adjacent stratum. Yet the upper portions of the confined air of the room will be found several degrees warmer than the lower. Instead of being divided only into opposite ranges, the whole mass, from the floor to the ceiling, will, in consequence of the expansion and buoyancy of its heated particles, form a series of intermediate strata, not distinguished, however, by

Proved by Experiment.

Climate. any very precise boundaries. But the intensity of action being proportional to the difference of temperature, the effect on the pyroscope must evidently be the same, whether it is produced by a single set of large pulses or by several sets of smaller ones. If, instead of one bounding surface, for example, above which the air is six degrees warmer than immediately below it, we suppose six such boundaries, each having an excess of temperature of only one degree; the pulses excited at the first of these intermediate surfaces, and successively augmented as they reach the second, third, and fourth, &c. surfaces, will at last acquire the same energy as if the aggregate difference of six degrees had been all exerted at once. Thus, the under surface of the stratum F darts pulses downwards, which, being augmented in succession at the under surfaces of the strata E, D, C, B, and A,

may have finally the same intensity as if they had originated from the apposition of the extreme strata F and A. Accordingly, having planted a large screen immediately before the fire, if a delicate pyroscope be placed about the middle of the room, and a broad circular piece of metal suspended a few inches above it; on withdrawing this canopy after some time, the instrument will indicate a small impression of heat, seldom exceeding, however, one degree. But the effect may be rendered more sensible by a moderate concentration of the power excited. Suppose a hemispherical shell of thin brass, or even planished tin, having a diameter about four times greater, adapted under the naked or sentient ball of the pyroscope, which might occupy, by its surface, the place of the diffuse focus, or the middle space between the centre and the bottom of the cup. Thus mounted, the instrument will now, in the same situation, mark a very sensible calorific impression, amounting, at least in ordinary cases, to 3 or 4 degrees. Hot pulses are, therefore, actually shot downwards from all the upper strata of the confined air of a room in which a fire is kept steadily burning.

Experiment varied.

The experiment can be likewise reversed. Let an inverted pyroscope, composed of a pendant differential thermometer, have its sentient ball fitted with a small hemispherical cup which is turned downwards. This instrument being set on the floor, will remain at zero; but if lifted only a few feet, it will indicate a visible impression of cold received from below, which will increase to 3 or 4 degrees when the pyroscope is suspended near the top of the room. Wherefore, the upper surfaces of the successive decumbent strata, being comparatively colder, send upwards a series of chilling pulsations. Each of the conterminous boundaries appears thus to perform a double operation, shooting downwards impressions of heat, and darting upwards equal impressions of cold. Such a mutual exchange of influence must evidently tend to accelerate that progress to an equilibrium which the gradual intermixture of

the different strata, if left quite undisturbed, would in time produce. The air of a close apartment exposed to the action of a steady fire, is hence kept agitated through its whole mass by a series of opposite tremors, which continually disperse, in all directions, the irregularities of temperature.

Climate.

If the action of the pulses excited in the air of a small room be made thus apparent, how much more striking should we expect to find the effect produced by the mingled tide of commotion collected in free space from the vast body of the atmosphere itself? Taking even the lowest range of strata, to the height perhaps of two miles, including scarcely one third part of the whole aerial mass, the difference of temperature between its extreme boundary will amount to 20 centesimal degrees, or 36 on Fahrenheit's scale. The order of the series, however, is exactly the reverse of what takes place in a close room, the air of the superior regions being invariably colder than at the surface of the earth. Accordingly, the simple pyroscope, exposed in calm weather to a clear and open sky, will, at all times, if not disturbed by the influence of a strong light, indicate large impressions of cold, amounting to 5 or perhaps even 10 degrees. In most cases, it may be sufficient to screen this instrument from the direct action of the sun's rays. But the action of light will be almost neutralized, by opposing a diaphanous ball to one gilt with silver, or contrasting a ball of the different shades of green or blue, to another coated with pure gold leaf. But to procure consistent results, it is still more necessary to guard against the deranging influence of winds.

Pyroscope described.

All these requisites are attained by adapting the pyroscope to the cavity of a polished metallic cup, of rather an oblong spheroidal shape, the axis, having a vertical position, being occupied by the sentient ball, while the section of a horizontal plane passing through the upper forms the orifice. The cup may be made of thin brass or silver, either hammered or cast, and then turned and polished on a lathe; the diameter being from two to four inches, and the eccentricity of the elliptical figure varied within certain limits according to circumstances. The most convenient proportion, however, is to have this eccentricity equal to half

Climate. the transverse axis, and, consequently, to place the focus at the third part of the whole height of the cavity, the diameter of the sentient ball being likewise nearly the third part of that of the orifice of the cup. In order to separate more the balls of the pyroscope, the gilt one may be carried somewhat higher than the other, and lodged in the swell of the cavity, its stem being bent to the curve, and the neck partially widened, to prevent the risk of dividing the coloured liquor in carriage. A lid of the same thin unpolished metal as the cup itself is fitted to the mouth of the æthrioscope, and only removed when an observation is to be made. The scale may extend to 60 or 70 millesimal degrees above the zero, and about 15 degrees below it.

This instrument exposed to the open air in clear weather will at all times, both during the day and the night, indicate an impression of cold shot downwards from the higher regions. Yet the effect varies exceedingly. It is greatest while the sky has the pure azure hue; it diminishes fast as the atmosphere becomes loaded with spreading clouds; and it is almost extinguished when low fogs settle on the surface. The name *ÆTHRIOSCOPE* (from *ἄθριος*, *sere-nus*, *sudus*, *frigidus*) may, therefore, be justly appropriate to this new combination of the pyroscope. The sensibility of the instrument is very striking, for the liquor incessantly falls and rises in the stem with every passing cloud. But the cause of its variations does not always appear so obvious. Under a fine blue sky, the *æthrioscope* will sometimes indicate a cold of 50 millesimal degrees; yet on other days, when the air seems equally bright, the effect is hardly 30°. Particular winds at different altitudes seem to modify the result, and so perhaps may the transition from summer to winter. Four months are scarcely elapsed since this instrument was first contrived, and during that time very few opportunities have occurred for making nice observations.

Another Form of that Instrument. The *æthrioscope* might be reduced to a smaller and more compact form, by conjoining with it a pendant differential thermometer. Neither of the glass balls in this case requires to be gilt; but the lower one is encased by a hollow sphere of brass, composed of two pieces which screw together, and the upper ball occupies the focus of the cup, which needs scarcely be more than two inches wide. This variety of the instrument is equally accurate, but, under any

Climate. change of temperature, rather slower in its action than the former.

On replacing the metallic lid, the effect is entirely extinguished, and the fluid in the stem of the differential thermometer sinks to zero. A cover of pasteboard has at first precisely the same influence; but after it has itself become chilled by this exposure, it produces a small secondary action on the sentient ball, scarcely exceeding, however, the tenth part of the naked impression. A lid of glass or of mica intercepts the impressions like one of paper; for the admission of light has no deranging effect if the *æthrioscope* be rightly constructed and highly polished. The minute secondary action is almost extinguished, if screens of paper, glass, or mica, be held at some distance above the mouth of the instrument.

In the first form of the *æthrioscope*, it is not essential, (though it augments the effect,) that one of the balls should be gilt, since the other being placed naked in the focus receives the pulses much concentrated. If both the balls were formed of black glass, the *æthrioscopic* impressions would evidently be blended with opposite photometrical ones. As long as the action of the light from the sky predominates, the instrument indicates an excess of heat; but after the pulses darted from the higher atmosphere come to prevail, it will mark the excess of cold. The liquor is stationary, when these contending influences are exactly balanced.

To ascertain whether the cold pulses are shot obliquely as well as in the vertical direction, the *æthrioscope* may be constructed to turn towards any portion of the sky. To effect this, the form best adapted for the reflexion would be that of an hyperbola, whose asymptotes have an inclination equal to the visual angle of the space to be explored. But to obtain accurate results, the focal ball must be small, and the hyperbolic conoid wide and much extended. It will answer nearly the same purpose, however, to adopt a truncated spheroid, of great eccentricity: Let the height of the focus, for instance, be one inch, that of the entire cavity nine inches, and, consequently, the widest diameter six inches. The figure on the other side is rather more distended, its extreme width being equal to double the eccentricity, and the focal ball dividing the height of the orifice in the ratio of 1 to $3 + \sqrt{8}$, or 6 to 35 nearly. While that sentient ball remains always in the same position, the axis of the instrument can, by means of a screw acting on the limb of a quadrant, be depressed or elevated to any given angle. But the effect will chiefly be produced by the direct impressions: for the lateral pulses, striking less obliquely against the cavity of the spheroid, will be feebly reflected. This moveable *æthrioscope* was placed in a convenient situation out of doors, when the sky appeared free from clouds, and had assumed a clear blue tint. The spheroid being turned first upright, the effect was noted; but this continued still unchanged, on depressing the axis successively, till it had approached the limit of energetic range, or within 20 degrees of the horizon.

(Climate.)

Frigorific Impressions the same in all Directions.

From every portion of the sky that subtends a given visual angle, there is hence received the same quantity of the frigorific pulses. But such would likewise be the result, if they were showered from the horizontal surfaces of the successive strata which divide the atmosphere; since although the intensity diminishes in the ratio of the sine of obliquity, a projecting space proportionally broader is for each elemental angle brought into action, as evidently appears from the annexed figure. This entire agreement between theory and observation is most satisfactory.

Influence of Clouds.

The same sectoral form of the æthrioscope discloses also the peculiar influence of clouds in obstructing the frigorific pulses excited in the atmosphere. When the sky was completely obscured by a dense canopy of clouds, the instrument being pointed to the zenith, marked only five millesimal degrees; but, on lowering it successively to the angle of 30 degrees above the horizon, it continued to indicate still the same effect. Water almost completely absorbs the pulsatory impressions of heat or cold; and may not clouds, consisting of diffuse aqueous particles, produce a similar effect? But the feeble action of five degrees, amounting scarcely to the eighth part of what is observed in clear weather, could not be any remnant of the pulses from the higher celestial regions, which had penetrated through the mass of vapours; because, if the vertical transit, through the obstructing range, allowed only an eighth part to escape, the oblique passage of 30 degrees, redoubling the extent of absorption, would have reduced the final discharge to five-eighths of a

degree. The impression measured by the æthrioscope, in this case, must therefore have originated wholly in the strata of air between the under surface of the clouds and the ground. But in that narrow space, the extreme difference of temperature would be comparatively small. Hence the frigorific action is found always to diminish as the clouds descend. Nor does their variable denseness appear materially to affect the result, which is often the least, when a very thin, whitish, but low vapour, gathers in the atmosphere. Hence the æthrioscope might, with great facility, be employed to estimate the altitude of clouds.

As the higher strata of the atmosphere thus dart cold pulses downwards, so the lower strata must evidently project equal pulses of heat upwards. But to measure these, it would require the æthrioscope to be inverted and furnished with a pendant pyroscope. The instrument, now carried to the top of a lofty mountain, and directed to the plain below, would indicate a considerable impression of heat, nearly proportional to the quantity of ascent; and, therefore, amounting, for example on the summit of Chimborazo, to perhaps 20 millesimal degrees. But, in the same situation, the common æthrioscope might be expected to mark a impression of cold from above, as just so much diminished. No opportunity, however, has yet occurred, on a large scale, for making these interesting observations. A balloon would afford the readiest mode of verifying the theory.

The inverted æthrioscope likewise discovers the quality and measure of the pulses projected from the ground. These, in general, are very feeble, seldom in this climate exceeding 3 or 4 degrees. In the progress of a bright day, as the ground grows warmer than the incumbent air, it excites hot pulses; but, as the sun declines, the effect gradually diminishes, till this again returns, increasing with a contrary character, when the surface of the earth has become relatively colder.

The same instrument being suspended a few feet above the ground while the sky appeared clear and blue, a silver tray was laid under it, and the reflected impression of cold amounted to 25 degrees, but, on interposing a plate of glass, it was reduced to 2 degrees; and on removing this, and pouring a sheet of water over the silver, the effect was absolutely extinguished. The absorbent influence of water, and consequently of clouds, was thus distinctly shown.

The nature and intensity of the cold and hot pulses excited in the several strata of the atmosphere, may be easily understood from the annexed figure. Let two equal and opposite circles touch the straight line AB, which divides a stratum of cold from another of warm air. While the diameters CD and cd represent the force of the per-

(Climate.)

Climate. pendicular pulses of cold darted downwards, and of heat upwards, the chords CF, CE, CH, and CG, and Cf, Ce, Ch, and Cg, will likewise exhibit the strength of the pulses which are shot obliquely.

Importance
of the Æth-
rioscope.

The æthrioscope thus opens new scenes to our view. It extends its through indefinite space, and reveals the condition of the remotest atmosphere. Constructed with still greater delicacy, it may perhaps scent the distant winds, and detect the actual temperature of every quarter of the heavens. The impressions of cold which arrive from the north, will probably be found stronger than those received from the south. But the instrument has yet been scarcely tried. We are anxious to compare its indications for the course of a whole year, and still more solicitous to receive its reports from other climates and brighter skies.

But the facts discovered by the æthrioscope are nowise at variance with the theory already advanced on the gradation of heat from the equator to the pole, and from the level of the sea to the highest atmosphere. The internal motion of the air, by the agency of opposite currents, still tempers the disparity of the solar impressions; but this effect is likewise accelerated by the vibrations excited from the unequal distribution of heat, and darted through the atmospheric medium with the celerity of sound. Any surface which sends a hot pulse in one direction, must evidently propel a cold pulse of the same intensity in an opposite direction. The existence of such pulsations, therefore, is in perfect unison with the balanced system of aerial currents.

The most recondite principles of harmony are thus disclosed in the constitution of this nether world. But we have left no room for pursuing the details. In clear weather, the cold pulses then showered entire from the heavens will, even during the progress of the day, prevail over the influence of the reflex light, received on the ground, in places which are screened from the direct action of the sun. Hence, at all times, the coolness of a northern exposure. Hence, likewise, the freshness which tempers the night in the sultriest climates, under the expanse of an almost constant azure sky. In our northern latitudes, a canopy of clouds generally screens the ground from the impressions of cold. But, within the arctic circle, the surface of the earth is more effectually protected by the perpetual fogs which deform those dreary regions, and yet admit the light of day, while they absorb the frigorific pulses, vibrated from the higher atmosphere. Even the ancients had remarked that our clear nights are generally likewise cold. During the absence of the sun, the celestial impressions continue to accumulate, and the ground becomes chilled to the utmost in the morning, at the very moment when that luminary again resumes his powerful sway. But neither cold nor heat has the same effect on a green sward as on a ploughed field, the action being nearly dissipated before it reaches the ground among the multiplied surfaces of the blades of grass. The lowest stratum of air, being chilled by contact with the exposed surface, deposits its moisture, which is either absorbed in-

VOL. III. PART I.

Climate. to the earth, or attracted to the projecting fibres of the plants, on which it settles in the form of dew or hoar frost. Hence the utility in this country of spreading awnings at night, to screen the tender blossoms and the delicate fruits, from the influence of a gelid sky; and hence, likewise, the advantage of covering walled-trees with netting, of which the meshes not only detain the frigorific pulses, but intercept the minute icicles, that, in their formation, rob the air of its cold.

The novelty and importance of the principles which regulate the distribution of heat in the atmosphere seemed to require a full discussion; but we have already outrun the space allotted for this article, and must, for the present, content ourselves with subjoining a few corollaries and general remarks. In a future part of this work we purpose to resume the consideration of the minor branches of the subject of Climate, and with more advantage, certainly, after the experiments and observations, now in progress, shall have come nearer to their conclusion. The relation of air to moisture will be treated under the word HYGROMETRY, and the complex phenomenon will receive a detailed explication under METEOROLOGY. Some farther views and illustrations may be given under PHYSICAL GEOGRAPHY, and other heads. The spontaneous arrangement and succession of the natural families of plants over the surface of the earth, in different latitudes and elevations, would alone form a very interesting article.

From what has been explained, it is easy to perceive, why the climate of an island should have a distinct character from that of a wide continent. The latter will experience a much greater range of heat and cold than the former, though the mean temperature, in like circumstances, will be the same in both. The proximity of the ocean quickly absorbs the inequality of the solar impressions. The passage from summer to winter is hence but feebly marked in detached islands. The prevalence, likewise, in such situations, of a land breeze during the day, and of a sea breeze during the night, especially near the tropics, reduces to very moderate limits the effects produced by the vicissitude of light and darkness.

The coldness of particular situations has very generally been attributed to the influence of piercing winds which blow over elevated tracts of land. This explication, however, is not well founded. It is the altitude of the place itself above the level of the sea, and not that of the general surface of the country, which will mould its temperature. A cold wind, as it descends from the high grounds into the vallies, has its capacity for heat diminished, and, consequently, becomes apparently warmer. The prevalence of northerly above southerly wind may, however, have some slight influence in depressing the temperature of any climate.

It has often been assumed as an incontrovertible fact, that the clearing of the ground, and the extension of agriculture, have a material tendency to ameliorate the character of any climate. But whether the sun's rays be spent on the foliage of the trees,

Climate

Cloud.

admitted to the surface of the earth, their accumulated effect in the course of a year, on the incumbent atmosphere, must continue still the same. The direct action of the light would, no doubt, more powerfully warm the ground during the day, if this superior efficacy were not likewise nearly counterbalanced, by exposure to the cooler sweep of the winds; and the influence of night must again re-establish the general equilibrium of temperature. The drainage of the surface will evidently improve the salubrity of any climate, by removing the stagnant and putrifying water; but it can have no effect whatever in rendering the air milder, as the ground will be left still sufficiently moist for maintaining a continual evaporation to the consequent dissipation of heat.

Much has been said of the comparative low perature of the American Continent. Its majestic rests, impervious to the solar beams, and its immense lakes, diffusing their vapours, are supposed sufficient to make the climate cold and damp; and the most splendid prospects have been delineated of those changes, which an active, free, and rapidly extending population, is destined to produce in reclaiming that vast region from the rankness of nature, and opening its soil to the genial influence of heaven. Much inaccuracy and exaggeration, however, has prevailed on this subject. The extremes of summer and winter probably differ more in America than in the old world, but the mere temperature on any parallel appears, when carefully taken, to be nearly the same. Thus, Mr Warden (*Chorographical Description of the District of Columbia, 1816*) found a spring in the vicinity of the capital of the United States, and therefore a little above the level of the sea, to mark 58° in Fahrenheit's scale; but two chalybeate springs in the same quarter, though perhaps deeper seated, showed a heat of 62° and 64° . Chalybeates are not deemed warm springs, or affected by their slight mineral ingredient. But on the same parallel of 39° , the mean temperature of the ancient Continent is $63\frac{1}{2}^{\circ}$.

Since the above was written, the third volume of the *Memoires de Physique et de Chimie* of the So-

ciety of Arcueil has reached us, containing, among other articles, an elaborate paper of the celebrated and accomplished traveller Baron Humboldt, *On Isothermal Lines, and the Distribution of Heat over the Globe*. Laying aside every theoretical consideration, this distinguished philosopher has here endeavoured to class the results of his own very numerous thermometrical observations with all those which he could collect from different quarters. The first difficulty that occurs is the mode of ascertaining the mean temperature of any place. It was found that half the sum of the maximum and minimum observed during the day and night, or through the summer and the winter, does not represent the true quantity. M. Humboldt has remarked that, between the parallels of 46° and 48° , the thermometer at the moment of sun-setting indicates in every season very nearly the medium temperature of the day. If this fact could be extended to other latitudes, it would greatly abridge the labour of meteorological observations.

From the data employed by M. Humboldt, he calculates that, corresponding to the latitudes of 30° , 40° , 50° , and 60° , the mean temperatures on the west side of the Old Continent are $70^{\circ}.5$, $63^{\circ}.1$, $50^{\circ}.9$, and $40^{\circ}.6$, but, on the east side of the New Continent, only $66^{\circ}.9$, $54^{\circ}.5$, 38° , and $42^{\circ}.2$. The isothermal lines, or lines of equal temperature, under the tropics run across the Atlantic nearly parallel to the equator; but, in the middle latitudes, they bend southerly towards the coast of America. These lines run nearly parallel into the interior of the New Continent, till they pass the Rocky Mountains, after which they bend again northwards. The climate is comparatively mild on the western shore of North America.

It is well known that the difference between the temperature of the winter and of the summer months increases in advancing from the equator to the pole. On the isothermal lines of 68° , 59° , 50° , and 41° , by Fahrenheit's scale, M. Humboldt estimates the extreme range of the year at 22° , 29° , $32\frac{1}{2}^{\circ}$, and 36° , on the Old Continent, and at 27° , 42° , $41\frac{1}{2}^{\circ}$, and 52° , on the New Continent.—But we must now conclude, in the hope of being able to resume this interesting discussion. (D.)

CLOUD.—Although the study of the clouds constitutes a very important branch of meteorological science, yet we do find that it occupied so much of the attention of ancient naturalists, as many other much less interesting atmospheric phenomena,—a circumstance which may possibly have arisen from the very great and almost endless variety of their external forms; in consequence of which they seemed, on a superficial view, to be incapable of being so arranged and classed, as to receive specific names whereby their varieties could be commemorated. Thus, meteorologists having no means either of accurately recording their own observations, or of benefiting by those of contemporary observers, made very little progress in the knowledge of these interesting phenomena; and the various figures of clouds were regarded as being the sport of winds, or of accidental circumstances not

demonstrably subject to general laws. In taking a slight survey of the observations of different writers, from the time of Aristotle to the present day, we shall see how very little progress was made in this branch of the science, till Mr Howard of London published his *Nomenclature and Observations on Clouds*. Different natural philosophers had made observations on certain properties of clouds; but no one had attempted a systematic description of them. Aristotle, in his work on *Meteorology*, seems to have been the first who attended to clouds. He remarked that they varied much in appearance; that they refracted different colours, at different times; that they possessed properties in their structure, capable, under peculiar circumstances of position with respect to the sun, of producing the phenomena of rainbows, halos, coronæ, the parhelia, &c. and he gave very minute

Climate

Cloud.

descriptions of these phenomena. He also notices the constant evaporation and reappearance of clouds, and gives it as his opinion, that clouds are taken into composition by the air, which, being decomposed again, the aqueous particles reassumed the forms of visible clouds. And this opinion, as we shall have occasion to notice hereafter, coincides with that of several eminent modern meteorologists.

Theophrastus, who had been the pupil of Aristotle, noticed, in a vague manner, some of the different forms of clouds, with respect, principally, to the prognostics of changes of the weather which might be deduced therefrom. He remarked, in particular, the appearance of strait horizontal sheets of clouds lodged on the summits of mountains, as an indication of wind and rain. His description of this kind of cloud corresponds so accurately with that called by the moderns *cirrostratus* or *wanecloud*, that it would be readily identified, even if the well known circumstance of its indicating a change to rainy weather did not render the description of this writer more clearly intelligible.

The modifications of clouds are as follows:—

CIRRUS or CURLCLOUD. Plate LVIII. fig. 1. Def. *Nubes tenuis flexuosa et undique crescens; altissimo aëre apparet.*

The great resemblance of some varieties of this cloud to a distended lock of hair, has suggested the name of *Cirrus*, of which *Cirrus* and the English *Curl* are the diminutives. The curling and flexuous forms of this cloud constitute its most obvious external character.

CUMULUS or STACKENCLOUD, fig. 7. Def. *Nubes annulata densa sursum crescens.*

This cloud is well known by its flattened base and cumulated irregularly hemispherical superstructure; hence its name *Cumulus*. The mode of its formation is by the gathering together of detached clouds into one large and elevated mass, hereafter to be spoken of. This mass, collecting all the fragments of newly formed cumuli in its vicinity, which seem as it were piled up, has received the name *Stackencloud*.

STRATUS or FALLCLOUD, fig. 9. Def. *Nubes strata vel aquæ modo expansa terræque procumbens.*

The term *Stratus* is applied to fogs, mists, and other extensive sheets of cloud which rest on the earth's surface. There are, however, some clouds which rest on the ground in the same manner as the *stratus*, which, in other particulars, resemble the *cirrostratus*, hereafter to be described. The *stratus* is generally formed by the subsidence, on the approach of evening, of the vapours carried into the atmosphere by the evaporation during the day. Hence the name *Fallcloud* has been used to distinguish this modification.

THE CIRROCUMULUS or SONDERCLOUD, fig. 2. Def. *Nubes constans e nubeculis subrotundis et quasi in agmini appositis.*

The *Cirrocumulus* consists of a number of little

orbicular masses of clouds, arranged in extensive beds, and it is to be distinguished from those features of the *Cirrostratus*, which most nearly resemble it, by the dense and compact form of its component *nubeculæ*. From the intermediate nature of this cloud, between the *cirrus* and *cumulus*, it has been called *Cirrocumulus*. It has received in English the name of *Sondercloud*, a word of Saxon derivation.

THE CIRROSTRATUS or WANECLLOUD, fig. 3, 4, 5. Def. *Nubes tenuis expansa evanescens, vel constans e nubeculis, hujus generis, in agmine appositis.*

The *Cirrostratus* is a cloud always distinguished by its flatness and great horizontal extension, in proportion to its perpendicular height. Under all its various forms, it preserves this characteristic, and is generally changing its figure, and slowly subsiding,—hence it is called the *Wanecloud*.—It often results from the fibres of the *cirrus* subsiding into strata of a more regularly horizontal direction; hence it is called *Cirrostratus*.

CUMULOSTRATUS or TWAINCLOUD, fig. 6. Def. *Nubes densa basin planam undique supercrescens vel constans e plurimis nubibus hujusce generis communem basin habentibus.*

The *Cumulostratus* is distinguishable from the simple *cumulus* by the greater degree of its density, and by its having frequently several large masses of cloud rising from a common base. This base is generally of a flat form, and floats on the surface of the vapour plane, like the base of the *cumulus*. Hence the name *cumulostratus*. The base being flat like a stratus, and the superstructure resembling a large *cumulus* overhanging its base, in large fleecy protuberances, or rising into the forms of mountains and rocks. This modification is called *Twaincloud*, from its often resulting from the visible coalescence of two other modifications, as for example the *cirrus* and *cumulus*. When it goes on increasing in density and size, it acquires the form and character of the *nimbus* (described below) becoming a raincloud, pouring down rain from its lower parts. (See fig. 8.)

NIMBUS or RAINCLOUD, fig. 8. Def. *Nubis vel nubium copia pluviam effundens.*

The *Nimbus* is the ultimate resolution and fall of clouds in rain, previous to which a change of form is observed in them, sufficiently remarkable to constitute a distinct modification.

Mr Howard began his observations about fifteen years ago, and Mr Forster of London has been for several years past employed in making corresponding observations. From all these observations there has resulted, at length, a theory of the formation and changes of the clouds, which has been deduced entirely from the phenomena they have been observed to exhibit during their formation, changes, and eventual resolution into rain. As we wish, however, to avoid, as much as possible, any particular hypothesis in this article, we shall give merely an accurate account of the phenomena observed, and content ourselves with a description of the distinct modification of form

Cloud.

which aqueous vapour is found to assume, during the progress of the formation, changes, and resolution of clouds.

The first general observation with regard to clouds is, that they have a tendency to assume one or other of seven distinct modifications, and that the peculiar character of these seven modifications may be discovered in all the endless configurations exhibited by clouds under different circumstances. It may be observed, further, that the most indefinite and shapeless masses of cloud, if attentively observed, will sooner or later show a tendency to take on the form of some of the modifications, a circumstance which shows not only their distinct nature, but also proves that there are some general causes, as yet undiscovered, why aqueous vapour, suspended in the air, should assume (though with great varieties of size, extent, and figure) certain definable and constant modifications.

We shall now proceed to a more minute description of the formation and changes of the clouds, and of the prognostics of future weather to be deduced from their peculiar appearances.

Formation, Changes, and Varieties of the Cirrus.

The *Cirrus* or *Curlicloud* may be distinguished from all others by the lightness of its nature, its fibrous structure, and the great and perpetually changing variety of figures which it presents to the eye. It is generally the most elevated of clouds, occupying the higher regions of the atmosphere. As this cloud, under different circumstances, presents considerable varieties of appearance, it will be proper to consider these separately, with reference to the particular kind of weather in which they prevail.

After a continuance of clear, fine weather, we often observe a fine whitish line of cloud, at a great elevation, like a white thread stretched across the sky, the ends of which seem lost in each horizon; this is often the first indication of a change to wet weather. To this line of cirrus others are added laterally; and sometimes clouds of the same sort are propagated, as it would seem, from the sides of the line, and are sent off in an oblique or transverse direction, so that the whole phenomena has the appearance of net-work. At other times, the lines of cirrus become denser, by degrees, descend lower down in the atmosphere, and by inoculating with others from below, produce rain without exhibiting the above described appearance of transverse masses of cloud.

To the above form of the curlicloud the name of *linear cirrus* has been given, and when the reticulated intersection is added to it, the name of *reticulated cirrus*, or net like curlicloud, has been applied to it as a mark of distinction.

The above mentioned varieties of the cirrus are all composed of straight lines of cloud either parallel or crossing each other in different directions, but they are ranged under the head of *cirrus* or *curlicloud*, from the analogy of their texture to this cloud when it appears under curling and contorted forms, which first suggested the name. The *comoid cirrus*, vulgarly called by the country people of Eng-

land the *mare's-tail cloud*, is the proper *cirrus*. It has somewhat the appearance of a distended lock of white hair, or of a bunch of wool pulled out into fine pointed ends, from whence it has derived its name, *comoid*. This form of the cirrus is most commonly an accompaniment of a variable state of the atmosphere, and often forebodes wind and rain. The direction of the fine and almost evanescent tails of this kind of cirrus, varies considerably in the course of a few hours, in very changeable weather; but when the tails have a constant direction towards the same point in the compass, for any considerable time, it has been frequently observed, that a gale has sprung up from that quarter to which they had previously pointed. In variable and warm weather in summer, when there are light breezes of wind, long and obliquely descending bands of cirrus are often observed in the air, and seem sometimes to unite distant masses of cloud together. Frequently, by means of the interposition of these cirri between a cumulus and some other cloud (as, for example, *cirrostratus*), the *cumulostratus* or twaincloud, and ultimately the *nimbus* or raincloud, is formed. If we attentively examine the *cirrus*, we shall find that it is in constant motion, not merely changing its form, but very often exhibiting a sort of internal commotion within the substance of the cloud, particularly in the larger end of it. Every particle seems alive and in motion, while the whole mass scarcely changes its place. This motion will, on a minute examination, often appear to consist of the fibres which compose the *cirrus*, gently waving backwards and forwards, to and from each other. Often, however, it seems like minute specks all in commotion. This takes place most frequently in those large and lofty cirri, with rounded heads and long pointed tails, which occur in general with dry easterly wind during the summer and autumn. (See fig. 1.)

Of the Formation and Changes of the Cumulus.

The best time for viewing the progressive formation of the *Cumulus* is in fine settled weather. If we then observe the sky about the time of sunrise, or soon afterwards, we shall see small specks of cloud here and there in the atmosphere. These often appear to be the result of small gatherings, or concentrated points of the stratus or evening mist, which, rising in the morning, grows into small masses of cloud, while the circumjacent atmosphere becomes clearer.

As the sun rises, these clouds get larger,—two or three perhaps which are near each other coalesce.—and at length a large cloud is formed, which, assuming a cumulated and irregularly hemispherical shape, has received the name of *cumulus* or *stackencloud*. This may properly be denominated the cloud of day, as it usually subsides in the evening, in a manner which forms the exact counterpart to its formation in the morning. It breaks up into small fragments and evaporates, and is succeeded again by the *stratus* or *fallcloud*, which has been called the cloud of night by some writers, on account of the period in which it prevails.

There are some varieties in the forms of the *Cumulus* which deserve particular notice, as they

Cloud.

Cloud. seem to be connected with electrical phenomena. In some kinds of fine weather, when these clouds form soon after sunrise, increase through the day, and subside in the evening, they are of a more hemispherical form, than when they occur in changeable weather. When these well-formed *cumuli* prevail during many days together, the weather is settled, and the atmospherical electrometer has been observed not to vary much in its indications. These *cumuli* are whitish-coloured, and reflect a fine strong silvery light when opposed to the sun. The *cumuli* which are seen in the intervals of showers are more variable in form, they are more fleecy, and have irregular protuberances. Sometimes they are of a blackish colour, like the clouds which the sailors call scud, and at other times they seem of a tuberculated form. *Cumuli* may, at any time, increase so as to obscure the sky, and they then generally inosculate and begin to assume that density of appearance which characterizes the twaincloud, or *cumulostatus*.

Of the Formation of the Stratus.

The *Stratus* or *Fallcloud* comprehends fogs, and all those creeping mists which in summer evenings fill the valleys, remain during the night, and disappear in the morning. The best time for observing its formation, is on a fine evening, after a hot summer's day. We shall then observe, that, as the *cumuli* which have prevailed through the day decrease, a white mist forms by degrees close to the ground, or extends only for a short distance above it. This cloud arrives at its density about midnight, or between that time and morning; and it generally disappears after sunrise. It is, for this reason, called by some writers the *cloud of night*. Under particular circumstances, it lasts longer in the morning than usual, particularly in autumn, the coming in of which season being generally marked by the greater prevalence of the fallcloud. In winter this cloud puts on a still denser appearance, and often lasts through the day, and even for many days successively; a remarkable instance of which occurred in the neighbourhood of London in January 1814. This fog spread over a large proportion of the south and west of England, and lasted about a fortnight. The *stratus* has often been found positively electrified, and its component particles do not wet leaves, or other substances connected with the earth. It has been supposed that the earth below it, and probably the air above it, contained a negative countercharge. The *stratus* should be distinguished from that variety of the *cirrostratus* or *wanecloud*, which looks much like it in external appearances, and which has usually a similar state of electricity with the earth. The criterion whereby we may judge to which of the two modifications to refer a mist is, that the *stratus* does not wet objects it alights on, but the *cirrostratus* moistens every thing.

Of the Formation and Changes of the Cirrocumulus or Sondercloud.

The *Cirrocumulus*, as has been said before, consists of a number of well-defined orbicular masses of cloud placed in close horizontal apposition, at the

same time being quite asunder, or separate from each other. It is subject, however, to some varieties in the size and figure of these orbicular masses, and in their nearer or more distant approximation to each other. The most striking feature of this cloud is observable before, or about the time of thunder-storms in summer. The component *nubeculae*, are then very dense in their structure, very round in their form, and in closer apposition than usual. See fig. 2. This kind of *Sondercloud* is so commonly a forerunner of storms, that it has been frequently spoken of by poets as a tempestuous prognostic. In rainy and variable weather, a variety of this cloud appears, strikingly contrasted with the abovementioned kind, being of a light fleecy texture, and having no very regular form in its *nubeculae*. Under these circumstances, it is sometimes so light and flimsy in its texture, as to approach very nearly to the nature of the *cirrostratus*. Sometimes this kind of *cirrocumulus* consists of *nubeculae* so small as scarcely to be discernible; the sky seems speckled with innumerable little round white, and almost translucent, spots. The *cirrocumulus* of fair summer weather is of a middle nature; neither being so dense as the stormy variety, nor so light as the one last described. Its *nubeculae* vary in size, and in the degree of their proximity. In certain kinds of fine dry weather, with light gales of north and easterly wind, small detachments of *cirrocumulus* rapidly form and subside again, which do not lie in one plane; but, in general, these clouds are in horizontal arrangement. The formation of *cirrocumulus* is either spontaneous, that is, unpreceded by any other cloud; or, 2d, it may result from the changes of some other modification. Thus the *cirrus* or *cirrostratus* often changes into *cirrocumulus*, and vice versa. When this cloud prevails, we may, in general, anticipate an increase of temperature in summer; and, in winter, it often precedes the breaking up of a frost, and indicates warm and wet weather. In warm weather, in the summer time, several extensive beds of this cloud, ranged in different altitudes, and viewed by moonlight, have a very beautiful and picturesque appearance, and have been compared by poets to a flock of sheep at rest. The *cirrocumulus* either subsides slowly, as if by evaporation, or it changes into some other modification of cloud.

Of the Formation, Varieties, and Changes of the Cirrostratus or Wanecloud.

The *Cirrostratus* is characterized by shallowness or great horizontal extent, in proportion to its vertical depth; so that when the *cirrus*, or any other cloud, is observed to assume this form, we may generally expect that it will end in a *cirrostratus*. The *cirrus*, for example, after having existed some time in the higher regions of the atmosphere, often descends lower; its fibres become more regularly horizontal; and it puts on, by degrees, the character of the *wanecloud*. The *cirrus* more frequently changes to the *cirrostratus* than the *cirrocumulus* does, and the *cirrocumulus* more frequently than the *cumulus*.

The *cirrostratus* being once formed, sometimes re-

Cloud.

Cloud.

assumes the character of the modification from which it originated, but it frequently it evaporates by degrees, or, by insculcation with some other modification, produces the twaincloud, and eventually falls in rain.

The *Cirrostratus* seldom remains long in the same form, but is observed to be constantly subsiding by degrees; hence it has been called the wanecloud from the old English verb to wane, to decline, or waste away. There are many varieties in the figure of the *cirrostratus*, some of which are more transitory than others. Sometimes the cloud is disposed in wavy bars or streaks, in close horizontal apposition, and these bars vary almost infinitely in size and shape. A flat and nearly horizontal cloud, composed of such streaks, is very common, particularly in variable weather, in summer. The bars, which composed this variety, are generally confused in the middle, and are most distinct towards the edges. See fig. 3. A variety not unlike this is seen in fine summer evenings, and constitutes what has been denominated the Mackerelback Sky. It is often very high in the atmosphere. We have observed, that, on ascending lofty mountains, the apparent distance of the cloud seems hardly diminished, while the *cumulus* or stackencloud has been sailing along on a level with the point of observation, or even below it. Another common variety of *cirrostratus* differs from the last in being one plane and long streak, thickest in the middle, and wasting away at its edges. This, when viewed in the horizon, has the appearance of fig. 5. It often seems to alight on the summits of the *cumulostratus*, as represented in the plate; and, in these cases, the density of the large twaincloud increases in proportion as these long waneclouds form and evaporate on their summit; a circumstance which looks as if the great density of the cloud depended on the insculcation and subsequent intermixture of the two different modifications with each other. The result of this intermixture, and the consequent density of the cloudy mass, is eventually the formation of the *nimbus* and the fall of rain. Another principal variety of the *cirrostratus*, is one which consists of small rows of little clouds curved in a peculiar manner. It is called the *Cynoid Cirrostratus*, and it is a sure indication of stormy weather. See fig. 4. Immediately below this, in the plate, is the representation of another less perfectly formed, having more of the character of the *sondercloud*. It is a variety often produced when a large *cumulus* passes under a long line of *cirrostratus*, like that in fig. 5., and is also a sign of variable and stormy weather. The last variety of *cirrostratus* to be mentioned, is that large and shallow veil of cloud which extensively over-spreads the sky, particularly in the evening and during the night, and through which the sun and moon but faintly appear. It is in this cloud that those peculiar refractions of the sun and moon's light, called Halos, Mocksuns, &c. usually appear, and which is the surest prognostic we are acquainted with, of an impending fall of rain or snow. To these principal varieties of the *cirrostratus*, others less frequent may be added, but as their forms are almost innumerable, every meteorologist must ob-

serve them for himself. The usual termination of the *cirrostratus* is, by forming an intimate union with some other cloud, to produce rain; but, at other times, it evaporates, or changes into some other modification, as observed above.

Cloud.

Of the Formation of the *Cumulostratus* or Twaincloud.

The *Cumulostratus* might be always regarded as a stage towards the production of rain, and it frequently forms in the following manner: The *cumulus*, which is common passes along in the current of wind, seems retarded in its progress,—increases in density,—spreads out laterally,—and at length overhangs the base in dark and irregular protuberances. The change to the *cumulostratus* often takes place at once in all the *cumuli* which are near to each other; and their bases uniting, while the superstructures remain asunder, rising up with mountain-like or rocky summits, the whole phenomenon has a fanciful appearance. The change from *cumulus* to *cumulostratus* is often preceded by the *cirrostratus*, or some other of the lighter modifications, coming over in an upper current and alighting on the summit of the *cumulus*. Long lines of wanecloud often appear for a length of time attached transversely to the summits of the twaincloud, and give them the appearance of being transfixed by shafts. See fig. 6. *Cumuli* sometimes meet together and begin to be arranged along with joined bases, without acquiring the dense black colour of the *cumulostratus*, and, as the change is gradual, we may view the cloud in an intermediate state. *Twainclouds* vary somewhat in appearance. Those in which hard hail showers and thunder storms form, look extremely black before the change to rain, and have a most picturesque but menacing aspect, as they are seen slowly coming up with the wind. The *cumulostratus* sometimes evaporates, or changes again to *cumulus*, and sometimes it forms itself spontaneously, without the preoccurrence of any other cloud, and disappears again. But, in general, it ends at last in the *nimbus*, and falls in rain. Frequently, in a long range of these clouds, one part changes into *nimbus*, and rains, while the other remains a *cumulostratus*. See fig. 8. But this is not frequently the case. Having given this sketch of the modifications, it must be observed, that masses of cloud sometimes appear hardly referable to any of them; but even then, if watched long enough, they will be found to put on sufficient of the character of some of the modifications to be registered under its name.

Of the Formation and Fall of the *Nimbus*, or Raincloud.

Hitherto we have considered only those modifications by which aqueous vapour is suspended, and kept as it were buoyant in the atmosphere. It remains now to describe a cloud which always precedes the fall of rain, snow, or hail, and which has been denominated *Nimbus*, agreeably to the notion of the ancients, who distinguish between the *imber* or a shower of rain, and the *nimbus* or cloud from which the rain came. Any of the six above described

modifications may increase so much as to obscure the sky, without ending in rain, before which the peculiar characteristic of the raincloud may always be distinguished. The best manner of getting a clear idea of the formation of the *nimbus*, is by observing a distant shower, in profile, from its first formation to its fall in rain. We may then observe the *cumulus* first arrested, as it were, in its progress, then a *cirrostratus* or *cirrus* may appear to alight on the top of it. The change to *cumulostratus* then goes on rapidly, and this cloud, increasing in density, assumes that black and threatening appearance which is a known indication of rain. Shortly afterwards the very intense blackness is changed for a more grey obscurity, and this is the criterion of the actual formation of water, which now begins to fall, while a *cirriform* crown of fibres extends from the upper parts of the clouds, and small *cumuli* enter into the under part. After the shower has spent itself, the different modifications appear again in their several stations; the *cirrus*, *cirrostratus*, or perhaps the *cirrocumulus*, appears in the higher regions of the air; while the remaining part of the broken *nimbus* assumes the form of flocky *cumulus*, and sails along in the current of wind which is next the earth. When large *cumulostrati* begin to appear again, they indicate a return of the rain; and these processes are constantly going on in showery weather, when the rapid formation and destruction of rain clouds goes on, and is attended by the other modifications in succession, in the manner above described. In continued rainy days, we cannot observe the upper parts of the *nimbus*, which extends for miles over large tracts of country; but we have no doubt that the same processes go on slower, and on a larger scale, in continued rainy weather, which are more conspicuous in the rapid and partial formation of showers.

From these descriptions, several practical conclusions follow:

1st, The modifications under different circumstances of position, with respect to the sun, refract different colours, which ought to be noted down in meteorological journals, as they appear to indicate different changes of weather; and future observations may either refute or confirm those from which, at present, doubtful indications are deduced.

2d, The prognostics of the coming weather must always be deduced from those clouds which ultimately prevail, and in the course of a day, almost all the modifications may be seen in variable weather.

3d, The prevalence of the *Wanecloud* is always a sign of a fall of rain or snow.

Future observations may possibly add new subdivisions to these seven distinct genera of clouds.

(c. o.)

COACH. The history of Coaches has been given in the body of the work. The following observations on the present taste in coach-making, are communicated by an eminent Manufacturer.

During the last twenty years, the improvements on coaches, landaus, chariots, &c. have been directed to the object of accelerating their speed in travelling, by diminishing their weight, and rendering their draught more easy.

It may be doubted whether the advantages acquired in this respect are not counterbalanced by the contraction of space in the inside, and by the want of magnificence on the outside, which carriages formerly possessed; at the same time it is acknowledged in all foreign countries, that, in point of neatness, easy draught, and elegance, the coaches, &c. of Britain far surpass all others.

The only late novelty deserving notice from its ingenuity or convenience, is the improved axle, made by Callinger and others, in which, by means of a broad groove in the axle, and a corresponding one in the box or bush, fitted to each other with extraordinary accuracy, and secured at the (out-head) or outer end by a double screw, the oil is retained during a journey of 500 miles or upwards, without the trouble or necessity of stopping to grease the wheels.

At present many of our young men of fortune plume themselves no less on their knowledge of the structure than on their proficiency in the art of driving these vehicles; and the *Whip*, or *Four-in-hand Club*, deserves to be mentioned here, as highly characteristic of the wealth and eccentricity of the British capital.

This association, consisting of above fifty members, who are each provided with an elegant coach, and four horses of the highest breed and price, harnessed and attached to it in the most expensive manner, together with one or two spare horses, and a full retinue of servants elegantly dressed, meets at stated periods; and each member, in the exact costume of a London coachman, drives his own carriage to a short distance from town, going or returning through the Parks, or most frequented streets and squares. The enormous expence incurred by every member of this showy establishment, if it was confined to itself, would be less to be deplored than it is. But the example of so many youths of high rank and great fortune has, as might be expected, diffused itself widely; and in the two Universities of Oxford and Cambridge, among those unable to rival the *Whip-Club* in splendid extravagance, the spirit of coach-driving displays itself in the endless and absurd variety of two-wheeled vehicles, in the structure and denominations of which, each candidate for chariot-teering fame strives to surpass his rival, till invention seems nearly exhausted. We have seen a vehicle called a *suicide*, from the extreme danger of driving it; and there are some aspiring youths, who have far eclipsed all their competitors, by driving through the most crowded streets in very high carriages, drawn by two horses, the one before the other, supported on one narrow wheel!

Notwithstanding the number and variety of carriages used in Great Britain, there are not many workmen employed, properly speaking, under the name of coach-makers. We have heard, and we believe on good authority, that their number does not exceed 3000 in the whole island. The various component parts of carriages are made by workmen bearing other denominations, such as wheelers, spring-makers, platers, lace-workers, &c. whose labours the coach-maker collects and combines for his own purpose.

It is merely doing justice to this employment to

Coak
Coalery.

state, that those engaged in the operative part of it have been no less remarkable for the decency and sobriety of their department, than those at the head of it have always been for great mechanical ingenuity.

COAK, or charred pitcoal, is prepared for the smelting of iron ore, by igniting the coals piled up in long ridges in the open air, and closing in the cinders with earth, when brought to a glowing red heat. For the use of the manufacturers, the method hitherto most in practice has been to burn the small or screened coal in conical ovens, built of firestone or brick; the floor is generally about six feet diameter, and the oven eight feet high, an aperture of 18 inches diameter being left at top. The small coal is thrown in to the depth of 15 inches or more, and then ignited. The oven-door is at first kept open, and the hole at top left uncovered till the mass is red-hot. The door is then closed, and, by degrees, the hole at top covered over by two large flat stones, gradually approaching each other, when the whole is left to cool. When sufficiently cooled, it is drawn out with long iron rakes, and the mass is found to have assumed a rude columnar arrangement, not much unlike starch. The oven is immediately charged again with small coal, which the heat remaining in the floor is found sufficient to ignite; and so the operation goes on. In both the above ways, good coaks are made, but the volatile products are lost. To save these, Lord Dundonald proposed to burn the coals in a close furnace, to which he adapted apparatus for conveying the coal-tar, with the ammoniacal products, into proper recipients. About the same time, Baron Von Haak, a German, constructed works in the neighbourhood of Newcastle for distilling the small coal in large cast iron cylinders, upon the plan which has since been adopted in the gas-light works; except that the soot from the furnace fires is, at Newcastle, during a certain period of the combustion, before any grey ashes have begun to arise, conveyed into a chamber contrived for the purpose, and collected for lamp-black; an economical practice, which does not appear to have been carried into the gas-works; and it is probable, that, as the practice of lighting our great towns with the carburetted hydrogen gas extends, most of the coak used in manufactures will be furnished in that way; but, as the coak thus produced will probably contain more sulphur, it is not likely that it will be fit for the smelting of iron-ore; the coak for which must, therefore, continue to be made in the old way. (P. P.)

COALERY. The article in the body of the work is perhaps one of the most useful essays that has hitherto appeared on this important subject. We shall therefore limit ourselves in this place to an account of some improvements as to the winning and working of coal, with which we have been favoured by an eminent Miner.

Of Winning. 1. What is generally called the winning of a coalery, is the draining of a field of coal, so as to render the several seams accessible, by pits to be sunk from the surface.

In order to determine the most eligible situation for a winning, it is requisite that the field of coal to be obtained by it, should have been previously ex-

plored by the methods described in the body of the work. Coalery.

Supposing the field of coal (see profile A, B, Plate LIX. fig. 1.) to have been explored by the borings *a, b, c, d*, and the crop of the seams *e*, and that it is determined to win the tract of coal in the seams C; D, extending from the ravine at *a*, to the crop of the seams at *e*.

In this case an adit or day-level drift or mine *r, f*, is set in from the ravine near to *a*, and is carried forward in a direct line until it cuts the seam C at *f*. This day-level drift also cuts the bore-hole *b* at *f*, by which the stratification from *b* to *f* is drained, and a coal-pit is then sunk upon the bore-hole *b, f*, from the surface to the seam C, with great facility.

In prosecuting the working of the coal from the pit *f*, towards the bore-hole C, a down-throw slip-dike *gg*, is met with, which depresses the seam C to E. The extent of this depression is ascertained by driving an horizontal stone-drift from where the seam C terminates at the dike *g g* to *h*, and by putting down the bore-hole *i*.

The day-level drift is then continued from *f* till it cuts the seam at E, and by carrying it forward to the bore-hole C, another coal-pit, *c, j*, is obtained in the same manner, as at *b*.

From *j* the working of the seam is carried on progressively until the upthrow slip-dike *kk* is met with. An horizontal drift is then extended from *l* to *m*, from which one boring is made upwards to the seam C, and another downwards to the seam D, by which the position of both seams is proved. The day-level drift may then be extended from the pit *c, j* through the dike *k k* into the seam D to *n*, to open out the bore-hole *d*, on which another coal-pit may be sunk through the seam C to the seam D, which may also be wrought by the pit *d n*, as well as the seam C.

The workings in both seams may now be carried on from the pit *d n* till they encounter the whin dike *o o*, which must be set through by carrying a drift through it on the same line of ascent as the seam leading to it, as dikes of this description seldom alter the level of the strata which they intersect. From the whin dike the working of both seams may be carried on without further difficulty to the crop of the coal at *e*.

This tract of coal, or coalery, may now be supposed to be wrought to the utmost extent that is available, by the day-level winning, and that it is determined to win the coal lying below this level by a steam-engine.

An engine pit F, G, is, therefore, sunk upon the day-level drift *f*, and through the seam C to D, below which the pump-well or lodge H is dug. After the sinking of the engine-pit is completed, a drift is carried forward towards the rise of the seam to L, where it will cut the bore-hole *b, f*, and allow the coal-pit to be sunk from *f* to L, and the dike *g g* having been already explored, the water course, or engine-level drift, is carried forward from the lodge at H, till it cuts the lower seam D at K, and thence forward in the seam D till it cuts also the bore-hole *c, j*, and the upthrow dike *k k* successively; by which

Coalery.

the whole extent of the seam D from G, by K to k, is drained and wrought by the pits *b* and *c* which have been sunk by the bore-holes discharging the water from them into the engine level.

It will be readily seen by referring to the profile, that the engine lifts the water no higher than the day-level drift *f*, by which it is discharged from the pump at *r* into the day-level drift, and thence into the ravine at *a*. The dip part of the upper seam C may also be won as far as S, by extending the engine level drift from the lodge H to S, as shown by the dotted lines.

This mode of winning coaleries can however only be pursued where the localities of the situation render it eligible; but as it frequently happens that coaleries are to be won where the surface of the ground is so nearly horizontal as not to admit of any benefit being derived from a day-level drift, it is necessary in such cases to draw the water to the surface by one or more steam-engines, as the case may require.

It frequently happens in situations of this kind, as in the neighbourhood of Newcastle-upon-Tyne, that great difficulties are encountered in the sinking through quicksands and very large feeders of water, some of which have been ascertained to communicate with the river Tyne.

The quicksands lie at various depths from the surface, as low as 30 fathoms and upwards; but the largest feeders of water are seldom met with at a greater depth than 50 fathoms. The quicksands vary much in thickness, as the feeders of water do in quantity; but a feeder which discharged nearly 4000 gallons *per* minute has been met with in one shaft. As it would be impracticable to draw such a quantity of water from the bottom of those deep mines but at an expence which could not be afforded, they are always stopped back by what is called tubbing and wedging, which is done by fixing water-tight cylinders of wood or cast iron within the circumference of the shaft, so as completely to dam back the water, and prevent its falling to the bottom of the pit. In some cases, water has been dammed back in this manner to the height of 70 fathoms, and at an expence of L.120 *per* fathom, or upwards. Quicksands are also passed through and dammed back by *tubs* or cylinders of wood or cast-iron, which are generally lowered down by ropes from the top of the pit, until they pass through the sand, and rest on the solid strata below.

As the sinking of pits under the above circumstances is attended with great expence and difficulty, no more are sunk than what may be barely necessary to work the destined part of coal below, and in some cases a whole coalery is wrought by one pit.

In situations of this kind, where the whole of the operations of the mine, as the drawing of coals and water, as well as the ventilation of the workings, are to be carried on by one pit, it follows that such pits must be made of large diameter, and divided into separate shafts.

They have therefore been sunk from 9 to 16 feet diameter, and divided into two, three, and four separate shafts by brattice, or partitions of deal

boards, according to the circumstances and extent of the mine.

Coalery.

Plate LIX. fig. 2. represents a pit of 9 feet diameter, which is divided by the brattice or partition *a*, *b*, into a coal shaft A, and an engine shaft B.

Fig. 3. represents a pit of 12 feet diameter, divided by the partitions *a*, *b*, *c*, into two coal shafts AA, and an engine shaft B.

Fig. 4. represents a pit of 16 feet diameter, divided into three coal shafts AAA, and an engine shaft B, by the partitions *a*, *b*, *c*, *d*.

In practice it has been found that the mode of dividing the shaft, as shown by fig. 2., is the most eligible.

Coaleries have been wrought to a great extent by pits of this description; the workings have been sometimes carried to the distance of two miles from the bottom, and the height of the air course has exceeded thirty miles. Several of the pits constructed in this manner in the Newcastle district exceed 100 fathoms in depth, and some are nearly 150 fathoms deep.

Most of these large double pits have powerful steam engines upon them, for pumping water; they are generally of Mr Watt's construction—double power—and usually exceed 100 horses' power, besides one or two more of the same construction for drawing coals, of from 20 to 30 horses' power.

As the principal feeders of water lie near the surface, the pumping engine is generally erected when the sinking commences. The pumps, which are now invariably made of cast iron, are suspended by ropes, and lowered down by capstans, as the sinking proceeds.

Rods of fir timber 6 or 7 inches square, called ground spars, are placed (according to the size of the pumps they have to bear), one on each side of the column (set) of cast-iron pipes, to which they are firmly tied at every 9 feet by cords, called *lashings*. A five-fold block is fixed to the top of each ground-spear, the tail-ropes or *falls* of which pass round capstans placed near the top of the pit, by which the column of cast-iron pipes in the pit can be raised or lowered at pleasure. A column of pipes, generally called a "set of pumps," suspended in this way, is as steady as if it was firmly fixed in a frame of timber. Pumps of 16 to 18 inches diameter may be carried to the depth of 50 fathoms in this way, if necessary; but in this case it is expedient to add a third pair of blocks.

It is, however, only in cases of necessity that columns of pipes of this length are suspended on ground-spears, and ropes, as, if circumstances will permit, the column of pipes ought to be firmly fixed in a cistern at the depth of 25 or 30 fathoms; but in many cases no dry situation can be met with in which to place the cistern, till the pit is sunk below the level of the large top-feeders, and consequently below the tubbing, in which it has not yet been found practicable to fix a cistern.

While the pipes are suspended in the manner above described, they are called sinking sets; after they are fixed on cisterns they are called standing sets.

Coalery.

Fig. 5. represents the method of suspending cast-iron pipes for sinking. *aa*, The iron blocks and ground ropes, with their falls *bb*, leading to the capstans placed in any convenient situation near the top of the pit.

dd, The iron UU's which connect the blocks with the tops of the ground-spears *ee*.

c, The hoggar-pump, generally made of fir-staves, and fixed by an iron flange and bolts to the uppermost cast-iron pipe. Always when the increased depth of the pit requires an additional pipe, the hoggar pump is taken off, and put on the top of the new pipe again.

f, The hoggar or leathern case, which delivers the water into the laundry box.

g, The flexibility of the hoggar enables it to accommodate itself to the gradual lowering of the pipes as the depth of the pit increases.

hh, The bottom rods which connect the ground-spears with the wind-bore of the pumps. The wings *ii* are cast upon the wind-bore, for the purpose of attaching the bottom rods to it by slots or bolts.

kkk, The lashings by which the pipes are fixed to the ground-spears.

m, The pump rod, wrought by the engine.

n, The snore-holes of the pump, which are plugged up, or kept open, as may be required by the sinkers.

Fig. 6. shows the method of fixing a standing set of pumps.

a, The bunton, made of the root end of a large oak, ten feet long and three feet square; but the larger the better. The inner end, which is the thickest, is placed in a recess cut in the stone, and the outer end is supported by an abutment of solid stone *b*, left in the pit.

The inner end of the bunton is firmly held down by wooden props, *cc*.

f, The cistern in which the pumps are placed, and into which the water from another set, either of sinking or standing pumps, may be delivered. The cistern is firmly fixed upon the bunton, and a recess is made in the side of the pit to receive it, and props *d* may be placed to fasten it down. The larger the cistern the better; there is no rule for regulating its size; but it ought, if possible, to be large enough to contain as much water as will supply its own pump, until the pump below delivers into it, when the engine begins to work.

g, The set of standing pumps placed in the cistern.

hhhh, The buntions with their cross collarings, *iiii*.

The buntions have one end fixed in the shaft wall, and the other is fastened to a cleat, *k*, which is nailed to the shaft brattice *ll*.

Fig. 7. shows a plan of the manner of fixing a bunton and cistern for supporting a stand-set of pumps.

aaaa Shows the recess cut in the side of the pit, with the bunton laid in its place. The inner end of the recess is cut dove-tailed, and the bunton wedged into it, so that it is prevented from moving forward by the shock of the pumps, when the engine is at work. The dotted lines show the situation of the cistern when placed on the bunton.

b, The pumps in the cistern.

cc, The situation in which the succeeding sets of pumps may be placed.

d, The main or shaft brattice.

e, The bunton to which the cross collarings *ff* are nailed, for securing the pumps in their proper position.

As all the operations of the engineers should be performed in the engine shaft, without interrupting the drawing of coals in the other shafts of a double pit, as much room as possible should be preserved in the engine shaft, by occupying as small a space in collaring the pumps as circumstances will permit.

For this purpose, iron stirrups have, for some time, been introduced in the place of cross collarings of wood, with great advantage.

If the cross collaring, *g*, fig. 7. was extended to the brattice, as shown by the dotted lines, and fixed to it by a cleat, in the same manner as the bunton *e*; by putting an iron stirrup round the pump with its ends passed through the collaring *g*, and fastened behind by the screw nuts *n*, the bunton *e*, and cross collarings *ff*, may be dispensed with, which will give much more room in the engine-shaft.

2. Thus far we have described the most improved methods of winning a coalery of considerable extent and depth. There are two distinct methods of working the coal, the narrow, and the long or broad way.

The narrow way is commenced by cutting passages through the coal, both lengthways and across, leaving rectangular pillars between the passages. By the first operation one-third of the coal is generally taken out; but where the strength of the coals and the firmness of the roof will permit, a greater or less proportion of the pillars which remain are afterwards removed, commencing with the most distant, and ending with those nearest the pit. By the broad way, the coal is wrought out at once, frequently for a length of 150 yards in one face, without leaving any pillars of coal to support the roof. The former method is adapted to beds of coal which occur at a considerable depth beneath the surface, from 50 to 150 fathoms; the latter to beds which lie nearer the surface, especially if they have a tolerably strong roof.

The mode of working by the narrow way, as generally practised both in the Scotch and English coaleries, and the general principle of ventilating works so wrought, are so fully described in the body of the work, that we find little to add in this place. But as an improved system has, within the last eight years, been brought to a state of high perfection, by the ingenious Mr Buddle of Wall's End, we are happy to be permitted to avail ourselves of the description of it, as given, under his correction, by Mr Griffith, in his excellent *Report on the Leinster Coal District*. By means of Mr Buddle's plan, from seven-eighths to nine-tenths of the coal is at present raised; whilst, eight years ago, but one-half, and frequently less, was all that could be obtained; and, therefore, through his exertions, the coal owners of the north of England may be said to have increased their property at least one-third; as more coal than is equal to that proportion, is now raised out of the

Coalery.

(Of the different Methods of Working)

Coalery. same area, than could be effected according to the old system.

Mr Buddle's ingenuity has not been confined to the improvement of the method of working coal; he has also introduced a more perfect system of ventilation; and has put in practice many simple but excellent contrivances, not only to prevent the accumulation of inflammable air in any part, but also by using hanging doors, which yield to the blast of inflammable air, and are not carried away, to prevent a general explosion throughout the mine when any cavity containing inflammable air is broken into accidentally, as the works extend; by this means, when the first blast is over, the lives of the colliers and horses in the distant parts are preserved. We shall, at present, confine ourselves to the different methods of working and supplying fresh air to the most distant parts of an extensive coalery, by one or more pits.

Plate LX. fig. 1. represents the plan of the improved system of working and ventilating coaleries in Newcastle-upon-Tyne.

The circle below the letter A is intended to represent a pit or shaft, divided from top to bottom by a boarded partition nicely joined, so as to prevent the communication of air from one side of the pit to the other. Through the right-hand division of this pit, which is called the *downcast*, the air descends. Having passed through all the excavations that have been made through the mine, which are represented by the white or uncoloured divisions, it passes up the left hand division of the pit. To aid the draught of air, a great fire is made in the furnace at B, which rarefies the air, and causes it to ascend more quickly through the upcast pit or division. The arrows point out the direction of the course of the air throughout the mine, and the red marks are walls or stoppings, built to force the passage of the air in particular directions. The dark coloured parts on the plate represent the unwrought part of the coal.

The principal advantage of the new mode of working is, that it divides the mine into any convenient number of districts, each of which is to be wrought out in its turn, and the roof suffered to close in. But to prevent the crush created by the falling in of the roof in one part, from communicating with and injuring the coal in another, a great protecting pillar or wall of coal is left between each division. By examining the figure, the several divisions or districts may be easily traced, by observing the line of large pillars.

The first operation of working the coal is represented clearly in the district E. From the bottom of the pit two parallel passages are cut, three yards broad and twelve yards asunder, at convenient distances; cross cut passages, or *headings* are driven to connect the parallel passages, and thereby create a complete circulation or current of air.

Coalery. The parallel passages are then continued until air again becomes deficient; a second heading is then cut, and the first is carefully closed up, so as to force the air round a lengthened circuit. This process is continued uninterruptedly round the district, as represented in fig. 1. The district being thus surrounded, broad passages, called *boards* or *rooms*, are then commenced at the lower end of the district, and are cut at regular distances upward, towards the parallel passages first described. The breadth of the boards, and that of the pillars of coal left between them, is continually varied, according to the nature of the strata which form the roof and floor of the mine. In the district F, the boards are represented in progress; this is also the case in the district K; when the boards and headings have been made throughout a whole district, this is represented by those of G and H. The next operation is to remove all the pillars; those at the farthest extremity of the district are first cut out; this operation is performed, either by commencing at one end, and proceeding regularly to the other, or by cutting the pillar in the middle, and setting a number of men to work at it. But this must depend on the strength of the roof. A few of the pillars of the district BG are represented as being removed, and the whole of the coal that could be carried away is represented as being wrought out of district I, nothing except the trifling quantity represented by the black lines being left behind. When the pillars of the district G have been wrought out nearly to the boundary pillar, between the districts I and G, the boundaries should be divided by boards and headways, and a considerable portion of them may thus be removed.

Owing to the frequent mistakes of sinking pits in improper situations, the pit A is placed in a position with respect to the coalery, that is frequently seen in practice, namely, a great part of the coal field lying to the dip, or under the natural water level of the pit. By observing the direction of the dip and rise, as represented on the plan by the great arrow, it is evident that, without some contrivance, no coal could be level or water-free below a line drawn across the pit A, at right angles to the arrow, and, consequently, half the coal of the districts F and G, and the whole of the district K, must have been left behind. To overcome this evil, the pit A is supposed to be sunk below the coal to a depth more than equal to the level of the coal at M, and a drift or passage is supposed to be horizontally cut through the strata beneath the bed of coal, till it meets the coal at M; by this means the district K may be freed from water. Had the pit been originally sunk nearer to M, all the expence and trouble of driving the stone drift would have been avoided.*

It frequently happens, that the stoppages or walls built to direct the ventilation, interrupt the communication from the various parts where the coal is

* There are, however, many reasons which may render it expedient, in particular cases, to avoid fixing the engine-pit on the lowest level of the coal-field, as when a slip or dike divides a small portion of the lower part of the field from the rest, &c. In this case, the coal wrought to the dip of the pit may easily be brought up to the drawing-pit by a high-pressure engine, fixed in some convenient station, at the head of an inclined plane.

Coalery. working to the pit bottom. When this happens, a door is placed at a convenient distance on either side of the wall, which may then be removed, and the leader of the coal waggons, as he passes along, opens the first door, and, having led his waggons past, shuts it, and then opens the second door, by which means the regular ventilation of the mine is constantly preserved.

According to the plan just described, very extensive coaleries are worked from one pit; and passages or boards, amounting in the aggregate to 30 miles in length, are perfectly ventilated by a single pit.

The mode of passing the air through the different passages or boards, varies according to circumstances. When a very quick current is required, the air is passed up one board and down the next; or as represented in the plate; or up two boards and down two, or up three boards and down three. But in small coaleries, or where no inflammable air is met with, the passages of air round the boundaries of a district, as that of F, leaving all the ends of the passages or boards open for the air to circulate, is found sufficient. At the great coaleries at Newcastle, the ventilation consists of a current of air of thirty-six square feet, moving with a velocity of three feet in a second.

The different modes of removing the pillars, according to circumstances, are represented in fig. 2. Plate LX.: *aa*, *cc*, *d* and *e*, are the different modes of working pillars where it is necessary to preserve the air courses. The pillars are wrought in the manner represented at *bb*, where the outer parts are much damaged and cracked by the pressure of the roof and floor. And *ff*, when the roof is not sufficiently strong to remain up, while the whole pillar is removing. In this case the centre part is left, and both ends are carried away.

The consequence of working the boards too wide is represented in the elevation, fig. 3. The pillars on either side of the board, *g*, are represented as much broken both at top and bottom by the pressure of the roof and floor, and the coal is rendered useless. Besides, the passage through the board is nearly closed by the approach of the roof and floor towards each other. The board *h'* represents the appearance in elevation, of one that is driven of a proper width. In this case, the coal on both sides is solid, and the roof and floor remain in their original positions. In working all coaleries, it is better to drive the boards too narrow than too broad; in the first case, when the pillars are to be removed, the roof and the coal are both sound, and the whole of it may with safety be removed; but, in the latter, the centre of the pillars only, as represented by *bb* in the plate, can be removed. As there is no account in the original article of the *broad method* of working; we shall, therefore, lay before our readers Mr Griffith's account of this method. A good account may also be found in Mr Farey's *Survey of Derbyshire*.

Many of the shallow and thin beds of coal in Yorkshire are worked in the broad way, but the breadth of the banks vary in almost every coalery, from certain local circumstances. We shall describe one, the principles of which may be applied to any shallow coalery, and the proper breadth of the banks,

which depend on the nature of the roof, will be determined better by practice than precept.

Fig. 4. represents a very simple and excellent method of working in the *broad way*. A shaft is divided into two parts, in the manner already described; *bbb* are double drifts, with proper headings for air; *cc* and *d* are banks, each thirty yards broad; the dotted marks represent three rows of wooden pillars which support the roof. The light shade represents the parts already worked out where the roof has fallen.

The first operation in the work is to drive the several double drifts. Those on each side of the pit must be completed to the full extent, before any other workings can go on. The three double drifts at right angles to the first may then be commenced; and, having advanced 20 or 30 yards, the great working or bank may be commenced, by breaking down the coal along the lines *cc* upwards. The coals are drawn from the face of the banks on both sides, through the openings or headings by which the air is introduced, as represented by the arrows. *l* and *f* are double doors to prevent the air from the left bank returning directly to the pit; by this means, it is forced along the face of the workings in the right bank. The first banks being proceeded on to a certain distance, a third and fourth may be commenced to the right and left, and others may be wrought to the rise, by connecting the rise drifts by cross ones at right angles to them, and working upwards from the cross drifts in the manner that has been described.

According to this plan, a very extensive coalery may be worked from one pit; but horses should be used to draw the coal under ground; and, if the coal be thin, part of either the floor or roof must be removed, to give sufficient headway. The most approved method of conveying the coals from the face of the work to the pit bottom is the following: First, a light cast iron railway must be laid from the pit bottom, through all the main passages of the coalery, and, branching from these, small moveable railways should be laid, from the nearest point of the main passage, or mother gate, as it is usually called, to the face of the workings. When the collier has broken down the coals, another man, known by the names of putter, hurrier, &c. is employed to fill the coal into a wicker basket, or wooden box, placed on a wooden carriage with iron wheels; this is pushed to the mother gate, along the railway, and the putter returns with an empty box, which has been placed in the mother gate; a waggon-boy arrives from the pit, leading a horse which draws six carriages chained together, each having an empty box on it. These boxes are lifted off; and, by means of a small crane, the full boxes are successively raised, and placed on the carriages, which, when thus laden, are drawn by the horse along the railway to the pit bottom, from whence the boxes are drawn up to the surface, and the empty ones returned.

The reader will find much useful information on the ventilation of mines in Mr Buddle's valuable tract, entitled, *The first Report of the Sunderland Society for preventing Accidents in Coal Mines*.

(F. F.)

COHESION.

Cohesion. **T**HE corpuscular forces, on which the mechanical properties of the aggregates of matter depend, have been in some measure considered, as far as they relate to solids, in the articles *BRIDGE* and *CARPENTRY* of this *Supplement* (P. 497, 622): there are however other modifications of these forces, which are principally exemplified in the *COHESION OF FLUIDS*; and which afford us a series of *phenomena*, highly interesting to the mathematician, on account of the difficulty of investigating their laws, and of considerable importance to the natural philosopher, from the variety of forms in which they present themselves to his observation.

SECTION I.—*Fundamental Properties of the Cohesion of a Single Fluid.*

The three states of elastic fluidity, liquidity, and solidity, in all of which the greater number of simple bodies are capable of being exhibited at different temperatures, are not uncommonly conceived to depend on the different actions of heat only, giving a repulsive force to the particles of gases, and simply detaching those of liquids, from that cohesion with the neighbouring particles, which is supposed to constitute solidity. But these ideas, however universal, may be easily shown to be totally erroneous: and it will readily be found, that the immediate effect of heat alone is by no means adequate to the explanation of either of the changes of form in question.

There can never be rest without an equilibrium of force: and if two particles of matter attract each other, and yet remain without motion, it must be because there exists also a repulsive force, equal, at the given distance, to the attractive force. If we imagined the atoms of matter to be impenetrable spheres, only resisting when their surfaces came into actual contact, it would follow, that the degree of repulsive force exerted at the same distance must be capable of infinite variation, so as to counterbalance every possible modification of the attractive force, that could operate between the particles. In this there would be no mathematical absurdity, and it may sometimes even be convenient to admit the hypothesis as an approximation: but we know from physical considerations that the actual fact is otherwise. The particles of matter are by no means incompressible: the repulsion varies indeed very rapidly when they approach near to each other; but the distance of the particles, and the density of the substance must inevitably vary, in some finite degree, from the effect of every force, that tends to produce either compression or expansion.

In elastic fluids, the law of the repulsive force of the particles is perfectly ascertained; and it has been shown to vary very accurately in the inverse ratio of their mutual distances. It is natural to inquire whether this repulsive force, continued according to the same law, would be capable of affording

Cohesion. the resistance exhibited by the same bodies in a liquid or solid form, and holding the cohesive force in equilibrium: but in order to answer this question, it would be necessary to determine the law of the variation of the cohesive force with the variation of the density. Now if this force extended to all particles within a given distance of each other, whatever the density might be, the number of particles similarly situated within the sphere of action being as the density, and each one of this number being attracted by an equal number, the whole cohesion urging any two particles to approach each other would obviously, as Laplace has observed, be as the square of the density: but since this cohesive force would increase, with the increase of density accompanying compression, more rapidly than any repulsive force like that of elastic fluids, there could never be an equilibrium between forces thus constituted: for, as Newton has justly remarked, the force of repulsion must be supposed to affect the particles immediately contiguous to each other only, their number not increasing with the density. Nor is there any reason to infer, from the phenomena of cohesion, that this force extends to a given minute distance, rather than to a given number of particles, as that of repulsion appears to do. It would indeed be possible to assign a law for the variation of cohesion, which would reduce the repulsion of liquids and of elastic fluids to the action of the same force, without any other modification than that which depends on the mutual distance of the particles; but this law is in itself so improbable, that it cannot be considered as affording an admissible explanation of the phenomena; for it would be required that the force of cohesion should diminish, instead of increasing, with every increase of density, and with a rapidity 19 times as great as the repulsion increased. For the height of the modulus of elasticity of all kinds of gaseous substances remaining unaltered by pressure, that of steam would still be only one twentieth as high as the modulus of elasticity of water, even if the steam were compressed by 1200 atmospheres; and the resistance to any minute change of dimensions would be twenty times as great in water as in steam of equal density, and the variation of the repulsion would be in the same proportion. It is therefore simplest to suppose the repulsion itself to be also twenty times as great, and the cohesion little or not at all altered by the effect of a slight compression or extension: and we shall have no difficulty in imagining this abrupt change in the magnitude of the repulsive force to depend on an increase of the number of particles to which it extends; supposing that when cohesion begins to affect them, this number becomes four or five times as great as before, and that it is not further increased by a greater increase of density; although, like the distance to which the force of cohesion itself extends, it may be liable to some modification from the

Cohesion. effects of a change of temperature. Thus it is probable that the number of particles co-operating, both in repulsion and in cohesion, is diminished by the effect of heat; for the diminution of the elasticity of a spring is much more than proportional to the expansion of its substance, although the primitive repulsive force of the single particles may very possibly be as much augmented by an elevation of temperature in this case as in that of an elastic fluid: the cohesive powers of liquids are also diminished by heat, and indeed in a considerably greater degree than the stiffness of springs, although there can be no doubt that there is a considerable analogy in these changes. However this may be, it appears that the force of cohesion cannot be supposed to vary much with the density, and it is therefore allowable to consider it as constant, at all distances, as far as its action extends; while that of repulsion, though it may operate in some degree at distances somewhat greater, may still be considered, on account of its greater intensity at smaller distances, as equivalent to a resistance terminating at a more minute interval than that to which the action of cohesion extends.

The distance at which cohesion commences between the particles of gaseous fluids appears to depend entirely on the temperature, and for any one fluid it is generally reduced to one half by an elevation of about 100° of Fahrenheit. In whatever way the particles are caused to approach nearer than this distance to each other, they become subject to the action of this force, and rush together with violence, and with a great extrication of heat, until the increased repulsion affords a sufficient resistance to the cohesion, and the gas is converted into a liquid. Superficial observers have sometimes imagined, that liquids possessed little or no cohesion; and it has generally been supposed that their cohesive powers are far inferior to those of solids. But that all liquids are more or less cohesive, is sufficiently shown by their remaining attached, in small portions, to every substance capable of coming into intimate contact with them, in opposition to the effect of gravitation, or of any other force: and the cohesion of mercury is still more fully exemplified by the well-known experiment of a column, standing at a height much exceeding that of the barometer, when it has been brought, by strong agitation or otherwise, into perfect contact with the summit of the tube, and is then raised into a vertical position; the summit of the tube supporting, or rather suspending the upper parts, and each stratum the stratum immediately below it, with a force determined by the excess of its height above that of the column equivalent to the atmospherical pressure. The perfect equality of the cohesion of a given substance in the states of solidity and liquidity, appears, however, only to have been asserted in very modern times; and the assertion has only been confirmed by a single observation of the sound produced by a piece of ice, compared with the elasticity exhibited in Canton's experiments on the compressibility of water; the results demonstrating that the resistance is either accurately or very nearly equal in both cases.

The real criterion of solidity is the lateral adhesion, which prevents that change of internal arrange-

ment, by which a fluid can alter its external dimensions without any sensible difference in the mutual distances of its particles taken collectively, and consequently without any sensible resistance from the force of cohesion. It is probable that this lateral adhesion depends upon some symmetrical arrangement of the constituent parts of the substance, while fluidity requires a total independence of these particles, and an irregularity of situation, affording a facility of sliding over each other with little or no friction. The symmetry of arrangement, when continued uniformly to a sensible extent, is readily discoverable by the appearance of crystallization; but there are several reasons for supposing it to exist, though with perpetual interruptions, in more uniform masses, or in amorphous solids. It is obvious that the lateral adhesion, confining the particles so as to prevent their sliding away, performs an office like that of the tube of a barometer to which the mercury adheres, or like that of the vessels employed by Canton and Zimmerman for confining water which is compressed; and enables the cohesive and repulsive powers of the substances to be exhibited in their full extent. Nor can we obtain any direct estimate of these powers from the slight cohesion exhibited, in some circumstances, by liquids in contact with the surface of a solid which is gradually raised, and carries with it a certain portion of the liquid; an experiment which had been often made, with a view of determining the mutual attractions of solids and fluids, but which was first correctly explained, as Laplace observes, by our countryman Dr Thomas Young, from its analogy with the phenomena of capillary tubes.

There are however still some difficulties in deducing these phenomena from the elementary actions of the forces concerned, whatever suppositions we may make respecting their primitive nature. The intermediate general principle of a hydrostatic force or pressure, proportional to the curvature of the surface, had been employed long ago by Segner, and had been considered by him as the result of corpuscular powers extending to an insensible distance only. But Segner's reasoning on this point is by no means conclusive, and he has very unaccountably committed a great error, in neglecting the consideration of the effects of a double curvature. There is also an oversight in some of the steps of the demonstration attempted by Dr Young in his *Lectures*, which has been pointed out by an anonymous writer in *Nicholson's Journal*: and Mr Laplace's final equation for determining the angle of contact of a solid and a liquid, which Dr Young had first shown to be constant, has been considered as completely inaccurate, and as involving an impossibility so manifest, as to destroy all confidence in the theory from which it was deduced. A demonstration, which appears to be less exceptionable, was lately published in the *Philosophical Magazine*; and it may serve, with some farther illustrations, for the present purpose.

It is only necessary to consider the actions of such of the particles of the liquid, as are situated at a distance from the surface shorter than that, to which the cohesive force extends; for all those, which are more internal, must be urged equally in all di-

Cohesion.

Cohesion. rections by the actions of the surrounding particles. Now it will readily be perceived, that the first or outermost stratum of particles will cohere very weakly with the stratum below it, having only its own attraction to bind it down; that the second will be urged by a force nearly twice as great; and that the cohesion will gradually augment, by increments continually diminishing, until we arrive at the depth of the whole interval to which the force extends: and below this it will remain constant, the number of particles within the given distance not undergoing any farther change. It has been observed by Mr Laplace, that this partial diminution of the density of the surface is likely to be concerned in facilitating the process of evaporation; and it has been cursorily suggested in another quarter, that the polarisation of light by oblique reflection may be in some measure influenced by this gradation of density. But its more immediate effect must be to produce that uniform tension of the surface, which constitutes so important a principle in the phenomena of capillary action; for since the cohesion in the direction of the surface is the undiminished result of the attractions of the whole number of particles constituting the stratum, acting as they would do in any other part of the substance, it follows that a small cubical portion of the liquid, situated in any part of the space which we are considering, will be pressed laterally by the whole force of cohesion, but above and below by that part only, which is derived from the action of the strata above it; so that this minute portion must necessarily tend to extend itself upwards and downwards, and to thicken the superficial film; and at the same time to become thinner in the direction of the surface, and to shorten it in all its dimensions: unless this alteration be prevented by some equivalent tension acting in a contrary direction: and this tension must be always the same in the same liquid, whatever its form may be, the thickness of the whole stratum being always extremely minute in comparison with any sensible radius of curvature.

Upon these grounds we may proceed to determine the actual magnitude of the contractile force derived from a given cohesion extending to a given distance. Supposing the corpuscular attraction equable throughout the whole sphere of its action, the aggregate cohesion of the successive parts of the stratum will be represented by the ordinates of a parabolic curve: for at any distance x from the surface, the whole interval being a , the fluxion of the force will be as $dx (a - x)$, since a number of particles proportional to dx will be drawn downwards by a number proportional to a , and upwards by a number proportional to x , and the whole cohesion, at the given point, will be expressed by $ax - \frac{1}{2}x^2$: and this at last becomes $\frac{1}{2}a^2$, which must be equal to the undiminished cohesion in the direction of the surface: consequently the difference of the forces acting on the sides of the elementary cube will everywhere be as $\frac{1}{2}a^2 - ax + \frac{1}{2}x^2$, and the fluxion of the whole contractile force will be $dx (\frac{1}{2}a^2 - ax + \frac{1}{2}x^2)$, the fluent of which, when $x = a$, becomes $\frac{1}{6}a^3$, which is one-third of $a \times \frac{1}{2}a^2$, the whole undiminished cohesion of the stratum.

We may therefore conclude in general, that the contractile force is one-third of the whole cohesive

Cohesion. force of a stratum of particles, equal in thickness to the interval, to which the primitive equable cohesion extends; and if the cohesive force be not equable, we may take the interval which represents its mean extent, as affording a result almost equally accurate. In the case of water, the tension of each inch of the surface is somewhat less than three grains: consequently we may consider the whole cohesive and repulsive force of the superficial stratum as equal to about nine grains. Now since there is reason to suppose the corpuscular forces of a section of a square inch of water to be equivalent to the weight of a column about 750,000 feet high, at least if we allow the cohesion to be independent of the density, their magnitude will be expressed by $252.5 \times 750,000 \times 12$ grains, which is to 9 as $252.5 \times 1000,000$ to 1; consequently the extent of the cohesive force must be limited to about the 250 millionth of an inch: nor is it very probable that any error in the suppositions adopted can possibly have so far invalidated this result, as to have made it very many times greater or less than the truth.

Within similar limits of uncertainty, we may obtain something like a conjectural estimate of the mutual distance of the particles of vapours, and even of the actual magnitude of the elementary atoms of liquids, as supposed to be nearly in contact with each other: for if the distance, at which the force of cohesion begins, is constant at the same temperature, and if the particles of steam are condensed when they approach within this distance, it follows that at 60° of Fahrenheit the distance of the particles of pure aqueous vapour is about the 250 millionth of an inch: and since the density of this vapour is about one-sixty thousandth of that of water, the distance of the particles must be about forty times as great: consequently the mutual distance of the particles of water must be about the ten thousandth millionth of an inch. It is true that the result of this calculation will differ considerably according to the temperature of the substances compared; for the phenomena of capillary action, which depend on the superficial tension, vary much less with the temperature than the density of vapour at the point of precipitation: thus an elevation of temperature, amounting to a degree of Fahrenheit, lessens the force of elasticity about one ten-thousandth, the superficial tension about one thousandth, and the distance of the particles at the point of deposition about a hundredth. This discordance does not, however, wholly invalidate the general tenor of the conclusion; nor will the diversity resulting from it be greater than that of the actual measurements of many minute objects, as reported by different observers; for example those of the red particles of blood, the diameter of which may be considered as about two million times as great as that of the elementary particles of water, so that each would contain eight or ten trillions of particles of water, at the utmost. If we supposed the excess of the repulsive force of liquids above that of elastic fluids to depend rather on a variation of the law of the force than of the number of particles cooperating with each other, the extent of the force of cohesion would only be reduced to about two-thirds; and on the whole it appears tolerably safe to conclude, that, whatever errors may have affected the determi-

Cohesion. nation, the diameter or distance of the particles of water is between the two thousand and the ten thousand millionth of an inch.

SECTION II.—Relations of Heterogeneous Substances.

We must now return from this conjectural digression to the regions of strict mathematical argument, and inquire into the effect of the contact of substances of different kinds on the tension of their common surfaces, and on the conditions required for their equilibrium. Whatever doubts there may be respecting the variation of the number of particles cooperating when the actual density of the substance is changed, there can be none respecting the consequence of the contact of two similar substances of different densities; for the less dense must necessarily neutralise the effects of an equivalent portion of the particles of the more dense, so as to prevent their being concerned in producing any contractility in the common surface: and the remainder, acting at the same interval as when the substance remained single, must obviously produce an effect proportional to the square of the number of particles concerned; that is, of the difference of the densities of the substances. This effect may be experimentally illustrated by introducing a minute quantity of oil on the surface of the water contained in a capillary tube; the joint elevation, instead of being increased, as it ought to be according to Mr Laplace, is very conspicuously diminished: and it is obvious that since the capillary powers are represented by the squares of the density of oil and of its difference from that of water, their sum must be less than the capillary power of water, which is proportional to the square of the sum of the separate quantities.

Upon these principles, we may determine the conditions of equilibrium of several different substances meeting in the same point, neglecting for a moment the consideration of solidity or fluidity, as well as that of gravitation, in estimating the contractile powers of the surfaces and their angular situations. We suppose then three liquids, of which the densities are A, B, and C, to meet in a line situated in the plane termination of the first: the contractile forces of the surfaces will then be expressed by $(A-B)^2$, $(A-C)^2$, and $(B-C)^2$: and if these liquids be so arranged as to hold each other in equilibrium, whether with or without the assistance of any external force, the equilibrium will not be destroyed by the congelation of the first of the liquids, so that it may constitute a solid. Now, unless the joint surface of the second and third coincides in direction with that of the first, it cannot be held in equilibrium by the contractility of this surface alone: but supposing these two forces to be so combined, as to produce a result perpendicular to the surface of the first substance, this force may be resisted by its direct attraction; the forces which tend to cause the oblique surface to move either way on it, balancing each other, and the perpendicular attraction being counteracted by some external force holding the solid in its situation. Consequently the force expressed by $(B-C)^2$, reduced in the proportion of the radius to the cosine of the angle, must become equal to the difference of

the forces $(A-B)^2$ and $(A-C)^2$, and if the radius be called unity, this cosine must be $\frac{(A-C)^2 - (A-B)^2}{(B-C)^2}$:

$$\frac{2AB - 2AC - (B^2 - C^2)}{(B-C)^2} = \frac{A - (B+C)}{B-C}, \text{ which is}$$

the excess of twice the density of the solid above the sum of the densities of the liquids, divided by the difference of these densities: and when there is only one liquid, and $C=0$, this cosine becomes $\frac{2A}{B} - 1$, vanishing when $2A=B$, and the density

of the solid is half of that of the liquid, the angle then becoming a right one, as Clairaut long ago inferred from other considerations. Supposing the attractive density of the solid to be very small, the cosine will approach to -1 , and the angle of the liquid to two right angles: and on the other hand, when A becomes equal to B, the cosine will be 1, and the angle will be evanescent, the surface of the liquid coinciding in direction with that of the solid. If the density A be still further increased, the angle cannot undergo any further alteration, and the excess of force will only tend to spread the liquid more rapidly on the solid, so that a thin film would always be found on its surface, unless it were removed by evaporation, or unless its formation were prevented by some unknown circumstance which seems to lessen the intimate nature of the contact of liquids with dry solids. For the case of glass and

mercury, we find $\frac{A}{B}$ about $\frac{1}{8}$, and the cosine $-\frac{7}{8}$,

which corresponds to an angle of 139° : and if we add a second liquid, the expression will become $\frac{-6-C}{8-C}$, which will always indicate an angle less

than 180° , as long as C remains less than 1, or as long as the liquid added is less dense than glass. There must, therefore, have been a slight inaccuracy in the observation mentioned by Mr Laplace, that the surface of mercury contained in a glass tube becomes hemispherical under water: and if we could obtain an exact measurement of the angle assumed by the mercury under these circumstances, we should at once be able to infer from it the comparative attractive density of water and glass, which has not yet been ascertained; although it might be deduced with equal ease from the comparative height of a portion of mercury, contained in two unequal branches of the same tube, observed in the air and under water. The cosine is more exactly $-.735$, in the case of the contact of glass and mercury, and

$$\frac{2A}{B} = .265, \text{ whence } \frac{A}{B} = \frac{1}{7.55}, \text{ which is a dispro-}$$

portion somewhat greater than that of the specific gravities; but it must probably vary with the various kinds of glass employed.

There is also another mode of determining the angle of contact of a solid with a single liquid, which has been ingeniously suggested by Mr Laplace; it is derived from the principle of the invari-

Cohesion.

Cohesion. ability of the curvature of the surface at a given elevation; and its results agree with those which we have already obtained, except that it does not appear to be applicable to the case of more than one liquid in contact with the given solid. Supposing a capillary tube to be partially inserted into a liquid, if we imagine it to be continued into a similar tube of the liquid, leaving a cylinder or column of indefinite length in the common cavity; then the action of either tube, upon the liquid immediately within it, will have no tendency either to elevate or to depress the column: but the attraction of the portion of the tube above the column will tend to raise it with a certain force, and the lower end of the tube will exert an equal force upon the portion of the column immediately below it; and this double force will only be opposed by the single attraction of the liquid continuation of the tube, drawing down the column above it; so that the weight of the column suspended will be as the excess of twice the attractive force of the solid above that of the liquid. Now supposing two plates of the solid in question to approach very near each other, so that the elevation may be very great in comparison with the radius of curvature of the surface, which in this case may be considered as uniform; the weight suspended will then be simply as the elevation, which will be the measure of the efficient attractive force, and will vary with it, if we suppose the nature of the solid to vary, the radius of curvature varying in the inverse ratio of the elevation: but the radius of curvature is to half the distance of the plates, as unity to the numerical sine of half the angular extent of the surface, or the cosine of the angle of the liquid, so that this cosine will be inversely as the radius, or directly as the elevation; that is, as the efficient attractive force, which is expressed by $2A - B$, becoming $= -1$ when A vanishes, and consequently being always equal to $\frac{2A - B}{B}$, as we have already found from

other considerations. If we wished to extend this mode of reasoning to the effect of a repulsive force counteracting the cohesion, we should only have to suppose the diameter of the tube diminished on each side by the interval which is the limit of the repulsion, since beyond this the repulsion could not interfere with the truth of the conclusions, for want of any particles situated in the given directions near enough to each other to exhibit it: and within the stratum more immediately in contact with the solid, the forces may be supposed to balance each other by continuing their action along its surface until they are opposed by similar forces on the outside of the tube or elsewhere: and indeed such a repulsive stratum seems in many cases to be required for affording a support to the extended surface of the liquid when the solid does not project beyond it. It may also be shown, in a manner nearly similar, by supposing the column to be divided into concentric cylinders, that the superficial curvature of the liquid will not affect the truth of the conclusion.

SECTION III.—Forms of Surfaces of Simple Curvature.

We may now proceed upon the principle, admitted

by all parties, of a hydrostatic pressure proportional to the curvature of the surface of the liquid, which is equivalent to a uniform tension of that surface, and which either supports the weight or pressure of the fluid within its concavity, or suspends an equal column from its convexity, whether with the assistance of the pressure of the atmosphere, or more simply, by the immediate effect of the same cohesion, that is capable of retaining the mercury of the barometer in contact with the summit of the tube: and on this foundation, we may investigate the properties of the forms assumed by the surface; first considering the cases of simple curvature, which are analogous to some of the varieties of the elastic curve, and next those of the surfaces having an axis of revolution, which will necessarily involve us in still more complicated calculations.

A. Let the height of the curve at its origin be a , the horizontal absciss x , the vertical ordinate y , the sine of the angular elevation of the surface s , the versed sine v , and the rectangle contained by the ordinate and the radius of simple curvature r ; then the area of the curve will be rs , and $y = \sqrt{a^2 + 2rv}$.

The fluxion of the curve z is jointly as the radius of curvature $\frac{r}{y}$, and as the fluxion of the angle of elevation, which we may call w , or $dz = \frac{r}{y} dw$, and

$$dx = \sqrt{1 - s^2} dz = \sqrt{1 - s^2} \frac{r}{y} dw; \text{ but } \sqrt{1 - s^2} =$$

$$dw = ds, \text{ consequently } dx = \frac{r}{y} ds, \text{ and } y dx, \text{ the}$$

fluxion of the area, becomes equal to rdx , and the area itself to rs . In order to find y , we have $dy =$

$$sdz = s \frac{r}{y} dw = \frac{r}{y} dv; \text{ whence } y dy = r dv, \text{ and } y^2 = 2rv + aa, y \text{ becoming equal to } a \text{ when } v \text{ vanishes.}$$

It may also be immediately inferred, that the area of the curve must vary as the sine of the inclination of the surface, from considering that, according to the principles of the resolution of forces, the tension being uniform, the weight which it supports must be proportional to that sine.

Scholium. The value of r for water at common temperatures, is about one hundredth of a square inch, according to the results of a variety of experiments compared by Dr Young; or more correctly, if we adopt the more recent measurement of Mr Gay-Lussac, .0115: for alcohol Mr Gay-Lussac's experiments give $r = .0047$; and for mercury $r = .0051$. Dr Young had employed .005 for mercury, a number which appears to be so near the truth, that it may still be retained for the greater convenience of calculation. Hence in a very wide vessel, the smallest ordinate a being supposed evanescent, and $y = \sqrt{2rv} = .1516 \sqrt{v}$, the height of the water rising against the side of the vessel, when $v = 1$, will be .1516; and the utmost height at which the water will adhere to a horizontal surface, raised above its general level, will be $2\sqrt{r} = .245$. For mercury, y becomes, in these circumstances, $\sqrt{.0102v} =$

Cohesion.

.101 \sqrt{v} , and if $s = .735$, $v = .322$, and the depression of the surface in contact with a vertical surface of glass becomes .0573; and again when $v = 1.735$, as in the case of a large portion of mercury lying on a plate of glass, the height y is .133; and if the glass had no attraction at all for mercury, v would become 2, and the height .1428. The actual tension of the surface of mercury is to that of water as $.0051 \times 13.6$ or .06936 to .0115; that is a little more than six times as great; while the angle of contact of mercury with glass, which is more attractive than water, would have led us to expect a disproportion somewhat greater. If we take a mean of these results, and estimate it at seven times, the value of \sqrt{r} will be reduced, by immersing mercury standing on

glass into water, in the ratio of $\frac{6}{7} \times \sqrt{\frac{13.6}{12.6}}$, since

the buoyant effect of the water increases the value of r , so that $\sqrt{(2r)}$ will be .09; and the angle approaching to 180° , the height will be about .127.

B. When the curve is infinite the absciss x becomes $= \frac{1}{2} \sqrt{r} \text{HL} \frac{2\sqrt{r} - \sqrt{(4r - yy)}}{2\sqrt{r} + \sqrt{(4r - yy)}} + \sqrt{(4r - y^2)}$, reckoning from the greatest ordinate $y = 2\sqrt{r}$; and the excess of the length of the curve above the absciss is $2\sqrt{r} - \sqrt{(4r - y^2)}$.

In this case, a being $= 0$, $y^2 = 2rv$: but $\frac{dx}{dy} =$

$$\frac{1-v}{s} : \frac{1-v}{\sqrt{(2v-rv)}} : \frac{2r-2rv}{\sqrt{(4r-2rv)}\sqrt{(2rv)}}$$

$\frac{2r-yy}{\sqrt{(4r-yy)y}}$; and, by the common rules for finding

$$\text{fluents, } x = \frac{2r}{4\sqrt{r}} \text{HL} \frac{2\sqrt{r} - \sqrt{(4r - yy)}}{2\sqrt{r} + \sqrt{(4r - yy)}} +$$

$\sqrt{(4r - y^2)}$; which vanishes when $y = 2\sqrt{r}$: and

for the length of the curve, since $\frac{dz}{dy} = \frac{1}{s} =$

$$\frac{1}{\sqrt{(2v-rv)}} = \frac{2r}{\sqrt{(4r-yy)}y}, \text{ subtracting the former}$$

fluxional coefficient from this, we have $\frac{ydy}{\sqrt{(4r-yy)}}$

for the fluxion of the difference; and the fluent of this is $-\sqrt{(4r - y^2)}$.

Corollary 1. Hence, where the curve is vertical, we find $x = .5328 \sqrt{r}$: and where the inclination amounts to a second, $x = 11.28 \sqrt{r}$; for example, in the case of water, \sqrt{r} being .1073, the latter value of x will become 1.21, and the former .056: so that the surface must be considered as sensibly inclined to the horizon at the distance of more than an inch from the vessel, but scarcely at an inch and a half: and for mercury, these distances will be two-thirds as great. This circumstance must not be forgotten when mercury is employed for an artificial horizon; although, where the vessel is circular, the surface becomes horizontal at its centre; and in other parts

the inclination is materially affected by the double curvature. Cohesion.

Corollary 2. The form of the surface coincides in this case with that of an elastic bar, or a slender spring, of infinite length, supposed to be bent by a weight fixed to its extremity; since the curvature of such a spring must always be proportional to its distance from the vertical line passing through the weight. We may therefore deduce from this proposition the correction required for the length of a pendulum like Mr Whitehurst's, consisting of a heavy ball, suspended by a very fine wire. Now the radius

of curvature of the spring is $\frac{Maa}{12fy}$ (Art. BRIDGE,

Prop. C); the modulus of elasticity, of which M is the weight, being for iron or steel about 10,000,000 feet in height; and since 80 inches of the wire weighed 3 grains, the thickness a , supposing it to have been $\frac{1}{3}$ or $\frac{2}{3}$ of the breadth, as is usual in wire flattened for hair springs, must have been about $\frac{1}{3}$ of an inch: the weight f was 12251 grains: and the

weight M of ten million feet must have been $\frac{3}{80} \times$

12×10000000 grains; consequently $\frac{Maa}{12fy}$

$$\times 10000000 \quad 1000$$

$$80 \times 12251 \times 375 \times 375y \quad 12251 \times 375y$$

$\frac{1}{4594y}$, which is analogous to $\frac{1}{y}$ in these propositions:

consequently $\sqrt{r} = \frac{1}{4594}$; and the whole value of $\sqrt{(4r - y^2)}$ from $y = 2\sqrt{r}$ to $y = 0$, is $\frac{1}{31}$ of an inch. Now supposing the spring to have been firmly fixed at the axis of vibration, the excess of its length above the ordinate will always be measured by $2\sqrt{r} - \sqrt{(4r - y^2)}$; but $\sqrt{(4r - y^2)} = \sqrt{(4r - 2rv)} = \sqrt{r}\sqrt{(4 - 2v)}$, which is the chord of the supplement of the arc of vibration in the circle of which the radius is $\sqrt{r} = \frac{1}{4594}$; and the ball will be drawn above its path to a height equal to the distance between this circle and another of twice the diameter, touching it at its lowest point: but a perpendicular falling from this point on the wire would always be found in a circle twice as much curved as the first circle, and if it were made the centre of vibration, the ball would always be raised twice as far above its original path as the distance between the first circle and the second, which is the measure of the effect of the curvature; so that the pendulum must be supposed to be shortened half as much as this; that is, in the present instance, $\frac{1}{135}$ of an inch: If however the spring remained in Mr Whitehurst's experiments, at liberty to turn within the clip, and was firmly fixed at a considerable distance above, the variation of the length must have been only that which belongs to half of the arc of vibration; that is, one fourth as great as in the former case, since the versed sine is initially as the square of the arc; but since it would affect the spring both above and below the clip, it would be doubled from this cause, and would amount to $\frac{1}{77}$ of an inch: so that the true correction would be liable to vary from .00735 to .00367, according

Cohesion. to the mode of fixing the wire. But since this error must have affected both Mr Whitehurst's pendulums in an equal degree, and the result was deduced from the difference, and not the proportion of the lengths, it is free from any inaccuracy on this account. The calculation however sufficiently proves the necessity of attending to the effect of different modes of fixing the spring, in order that no variation may be made in the different experiments compared without a proper correction. The elasticity of such a wire, as Mr Whitehurst employed, could not have produced any sensible error, by co-operating with the force of gravitation, since it did not amount to one two-millionth part of the weight of the ball.

C. The relation of the ordinate and absciss may be generally expressed by means of an infinite series.

When the curve is concave towards the absciss throughout its extent, the ordinate may be compared with the lengths of hyperbolic and elliptic arcs, as Maclaurin has shown with respect to the elastic curve (*Fluxions*, § 928): but his solution fails in the more ordinary cases of the problem; and even where it is applicable, the calculation is very little facilitated by it. Segner has made use of two different forms of infinite series, each having its peculiar advantages with respect to convergence in particular cases, and other forms may be found, which will sometimes be more convenient than either of these.

The value of the cotangent $\frac{dx}{dy}$ being in general

$$\frac{1-v}{\sqrt{(2v-vv)}} = \frac{2r-2rv}{\sqrt{(4r-2rv)} \sqrt{(2rv)}} = \frac{2r-yy+aa}{\sqrt{(4r-yy+aa)} \sqrt{(yy-aa)}}, \text{ we may retain either of these fractions, and expand the other by means of the binomial theorem.}$$

1. In the first place, making $4r+a^2=c^2$, we have $(c^2-y^2)^{-\frac{1}{2}} = \frac{1}{c} + \frac{1}{2} \cdot \frac{y^2}{c^3} + \frac{3}{4.2} \cdot \frac{y^4}{c^5} + \frac{5}{8.2.3} \cdot \frac{y^6}{c^7} + \dots$, and $\frac{dx}{dy} = \frac{2r+aa}{\sqrt{(yy-aa)}}$

$\left(\frac{1}{c} + \frac{1}{2} \cdot \frac{y^2}{c^3} + \frac{3}{4.2} \cdot \frac{y^4}{c^5} + \dots \right) \cdot \frac{1}{\sqrt{(yy-aa)}} \cdot \left(\frac{y^2}{c} + \frac{1}{2} \cdot \frac{y^4}{c^3} + \frac{3}{4.2} \cdot \frac{y^6}{c^5} + \dots \right)$. Now, in order to find the fluents of the separate terms, we have first $\int \frac{dy}{\sqrt{(yy-aa)}} = \text{HL} (y + \sqrt{[yy-aa]})$; and calling this logarithm L,

$$\int y^2 \frac{dy}{\sqrt{(yy-aa)}} = \frac{y}{2} \sqrt{(y^2-aa)} + \frac{a^2}{2} L;$$

$$\int y^4 \frac{dy}{\sqrt{(yy-aa)}} = \left(\frac{y^3}{4} - \frac{3a^2y}{8} \right) \sqrt{(y^2-aa)} + \frac{3a^4}{8} L;$$

$$\int y^6 \frac{dy}{\sqrt{(yy-aa)}} = \left(\frac{y^5}{6} - \frac{5a^2y^3}{24} + \frac{5a^4y}{16} \right) \sqrt{(y^2-aa)} + \frac{5a^6}{16} L; \text{ and}$$

$$\int y^8 \frac{dy}{\sqrt{(yy-aa)}} = \left(\frac{y^7}{8} - \frac{7a^2y^5}{8.6} + \frac{7.5a^4y^3}{8.6.4} - \frac{7.5.3a^6y}{8.6.4.2} \right) \sqrt{(y^2-aa)} + \frac{7.5.3a^8}{8.6.4.2} L: \text{ whence}$$

$$\text{by substitution we have } x = \frac{2r+aa}{4r+aa} L +$$

$$\left(\frac{2r+aa}{2(4r+aa)^3} + \frac{1}{4r+aa} \right) \cdot \left(\frac{y}{2} \sqrt{(y^2-aa)} + \frac{a^2}{2} L \right) + \dots$$

2. If we reduce $\frac{1}{\sqrt{(yy-aa)}}$ into a series, we

$$\text{have } \left(1 - \frac{aa}{yy} \right)^{-\frac{1}{2}} = 1 + \frac{1}{2} \cdot \frac{a^2}{y^2} + \frac{3}{4.2} \cdot \frac{a^4}{y^4} + \frac{5}{8.2.3} \cdot \frac{a^6}{y^6} + \dots, \text{ and } \frac{dx}{dy} = \frac{2r+aa-yy}{\sqrt{(cc-yy)}} \cdot \left(\frac{1}{y} + \frac{1}{2} \cdot \frac{a^2}{y^3} + \frac{3}{4.2} \cdot \frac{a^4}{y^5} + \dots \right). \text{ Then, for the fluents,}$$

$$\int \frac{ydy}{\sqrt{(cc-yy)}} = \sqrt{(c^2-y^2)}; \int \frac{dy}{y \sqrt{(cc-yy)}} =$$

$$\text{HL } \frac{c - \sqrt{(cc-yy)}}{c + \sqrt{(cc-yy)}} = L;$$

$$\int \frac{dy}{y^3 \sqrt{(cc-yy)}} = -\frac{\sqrt{(cc-yy)}}{2cyy} - \frac{1}{2cc} L;$$

$$\int \frac{dy}{y^5 \sqrt{(cc-yy)}} = \left(-\frac{1}{4c^2y^4} + \frac{3}{8c^4y^2} \right) \sqrt{(c^2-y^2)} + \frac{3}{8c^4} L;$$

$$\int \frac{dy}{y^7 \sqrt{(cc-yy)}} = \left(-\frac{1}{6c^2y^6} + \frac{5}{24c^4y^4} - \frac{5}{16c^6y^2} \right) \sqrt{(c^2-y^2)} - \frac{5}{16c^6} L; \text{ and by combining these}$$

fluents we obtain a second series for x.

3. These series may be employed with advantage where the initial ordinate is very small, the one being more convenient for the upper, and the other for the lower part of the curve: but where the elevation a is more considerable, the form of the curve will be more readily determined by means of fluents derived from circular arcs. Beginning with the ex-

pressions $\frac{dx}{dy} = \frac{1-v}{\sqrt{(2v-vv)}}$, and $y^2 = a^2 + 2rv$, we

may seek for a value of x in terms of v; and since

$$2ydy = 2r dv, \text{ dy} = \frac{r}{y} dv = \frac{r dv}{\sqrt{(aa+2rv)}}, \text{ and } dx =$$

$$\frac{1-v}{\sqrt{(2v-vv)}} \cdot \frac{r dv}{\sqrt{(aa+2rv)}} \cdot \frac{1}{\sqrt{(aa+2rv)}}. \text{ The binomial } (aa+2rv)^{-\frac{1}{2}}$$

may then be expanded into a series of integral powers of v, and the fluents may be found by means

of the equations $\int \frac{dv}{\sqrt{(2v-vv)}} = \int \frac{dv}{s} = w$, the arc

Cohesion.

of which v is the versed sine; $\int \frac{v dv}{s} = s - w$; $\int \frac{v^2 dv}{s}$
 $= \left(\frac{v}{2} - \frac{3}{4} \cdot \frac{v^3}{8} \right) s + \frac{3}{8} \cdot \frac{v^4}{4} w$; $\int \frac{v^3 dv}{s} =$
 $\left(\frac{v^2}{3} - \frac{5}{24} \cdot \frac{v^4}{4} + \frac{5}{16} \cdot \frac{v^6}{8} \right) s - \frac{5}{16} \cdot \frac{v^7}{8} w$; and $\int \frac{v^4 dv}{s}$
 $= \left(\frac{v^3}{4} - \frac{7}{8.6} \cdot \frac{v^5}{5} + \frac{7.5}{8.6.4} \cdot \frac{v^7}{7} - \frac{7.5.3}{8.6.4.2} \cdot \frac{v^9}{9} \right) s$
 $+ \frac{7.5.3}{8.6.4.2} \cdot \frac{v^{10}}{10} w.$

4. Another series may be obtained by the expansion of $\frac{1}{\sqrt{(2v-vv)}}$ into $\frac{1}{\sqrt{(2v)}}$

$\left(1 + \frac{1}{4}v + \frac{3}{8.2}v^2 + \frac{5}{16.2.3}v^3 + \dots \right)$, whence
 $\frac{dx}{dy} = \left(1 - \frac{yy-aa}{2r} \right) \sqrt{\frac{r}{yy-aa}}$
 $\left(1 + \frac{1}{4} \frac{yy-aa}{2r} + \frac{3}{8.2} \left(\frac{yy-aa}{2r} \right)^2 + \dots \right)$: the
fluxions belonging to the series $(y^2 - a^2) - \frac{1}{2}dy$,
 $(y^2 - a^2)^{\frac{1}{2}}dy$, $(y^2 - a^2)^{\frac{3}{2}}dy$; and the fluents of
these are HL $(y + \sqrt{[y^2 - a^2]}) = L$; $\frac{1}{2}y\sqrt{(y^2 - a^2)}$
 $- \frac{1}{2}a^2L$; $\left(\frac{1}{4}\sqrt{(y^2 - a^2)} + \frac{3}{8}a^2 \right) y\sqrt{(y^2 - a^2)} +$
 $\frac{3a^4}{8}L$; which afford a result somewhat resembling
that which is deduced from the first method.

5. We may also express x in a series of integral powers of y only, if we suppose it to begin at some point in which the curve is inclined to the horizon, where the height is p , calling it at other points $p+y$, and making $\frac{dx}{dy} = r = a + by + cy^2 + \dots$; we have then $x = \beta + ay + \frac{1}{2}by^2 + \frac{1}{3}cy^3 + \dots$, and the area $\int (p + y) dx = \gamma + pay + \frac{1}{2}pby^2 + \dots + \frac{1}{2}ay^2 + \frac{1}{2.3}by^3 + \frac{1}{3.4}cy^4 + \dots$, which must be equal to rs

(Prop. A.): but $s = \frac{dy}{\sqrt{(dx^2 + dy^2)}} = \frac{1}{\sqrt{(1 + r^2)}}$, which may be developed by means of the Taylorian theorem
 $\phi(A + H) = \phi A + \frac{d(\phi A)}{dA} H + \frac{d^2(\phi A)}{dA^2} \cdot \frac{H^2}{2} + \dots$,
taking $A = a$, and $H = by + cy^2 + \dots$, whence
 $H^2 = b^2y^2 + 2bcy^3 + (2bd + c^2)y^4 + \dots$
 $H^3 = b^3y^3 + 3b^2cy^4 + \dots$; consequently $rs = rpa \dots$

$= \frac{r}{\sqrt{(1+aa)}} + \frac{r}{da} \cdot d \frac{1}{\sqrt{(1+aa)}} (by + cy^2 + dy^3 + cy^4 + \dots)$
 $+ \frac{r}{2da^2} \cdot d^2 \frac{1}{\sqrt{(1+aa)}} \cdot (b^2y^2 + 2bcy^3 + (2bd + c^2)y^4 + \dots)$

Cohesion.

$+ \frac{r}{2.8da^3} \cdot d^3 \frac{1}{\sqrt{(1+aa)}} (b^3y^3 + 3b^2cy^4 + \dots) =$
 $+ pay + (\frac{1}{2}pb + \frac{1}{2} \frac{da}{dt} \frac{dy}{dt})$
 $+ (\frac{1}{2}pc + \frac{1}{2}b^2)y^3 + \dots$; and hence by comparing the homologous terms, we find $\gamma = \frac{r}{\sqrt{(1+aa)}}$,
 $\frac{r}{da} \cdot d \frac{1}{\sqrt{(1+aa)}} \cdot b = pa = \frac{-ra}{(1+aa)^{\frac{3}{2}}} \cdot b$, and $b =$
 $\frac{p}{r} (1+aa)^{\frac{3}{2}}$; and in a similar manner we may determine the subsequent coefficients; but the calculation is somewhat laborious, and has no particular advantages.

6. We may still more readily obtain a similar series for y in terms of the powers of x with constant coefficients; calling $\frac{dy}{dx} = t$, and making $t = bx + cx^2 + dx^3 + \dots$ whence $y = a + \frac{1}{2}bx^2 + \frac{1}{4}cx^4 + \frac{1}{6}dx^6 + \dots$, and the area $\int y dx = ax + \frac{1}{2.3}bx^3 + \frac{1}{4.5}cx^5 + \dots = rs = \frac{rt}{\sqrt{(1+tt)}} = rt(1 - \frac{1}{2}t^2 + \frac{3}{4.2}t^4 - \frac{5}{8.2.3}t^6 + \dots)$. But $t^3 = b^3x^3 + 3b^2cx^5 + \dots$ and $t^5 = b^5x^5 + \dots$; hence we have the equation

$\frac{ax}{r} + \frac{1}{2.3r}bx^3 + \frac{1}{4.5r}cx^5 + \dots =$
 $bx + cx^2 + \frac{dx^3}{2} + \dots$
 $-\frac{1}{2}b^3x^3 - \frac{1}{2} \cdot 3b^2cx^5 - \dots$
 $+\frac{3}{8}b^5x^5 + \dots$; consequently
 $b = \frac{a}{r}$, $c = \frac{1}{2.3r}b + \frac{1}{2}b^3$, and $d = \frac{1}{4.5r}c + \frac{5}{2}b^2c - \frac{5}{8}b^5$.

It is the less necessary to enter into any further detail of these results, as we have a table, calculated by Segner, with his son's assistance, which is sufficient to afford us a general idea of the forms of the curve in different circumstances. The unit of this table is the quantity \sqrt{r} , which Segner calls the modulus of capillary attraction, and which for water is .1072 inch. The table begins with the extreme ordinate, where the curve is vertical: we have then the least ordinate, a ; the greatest ordinate, where the curve again becomes horizontal, and the absciss corresponding to the extreme ordinate and to the greatest ordinate.

It may be observed that the last six values of the least ordinate are in geometrical progression, while the absciss increases in arithmetical progression; the difference of the absciss 2. 3, being the hyperbolic logarithm of 10, which is the common multiplier of the ordinates. Although the table appears to be generally accurate, yet we cannot always depend on the last figures: thus the ultimate difference of the two last columns is made .43, while it ought to be .53 (Prop. B. Cor. 1). It is scarcely necessary to remark, that if we look, in the fourth column, for half the distance between two parallel planes of glass, in a vertical position, the first and second columns will give us the height to which water will rise between them, where it touches the glass, and in the middle of the interval.

SECTION IV.—Surfaces of Double Curvature.

When the liquid is contained in a tube, or when it forms itself spontaneously into a drop having an axis of revolution, it becomes necessary to consider the effect of the tension in a direction transverse to that of the principal section; since the curvature

will cause it to exhibit an equal pressure, whatever the direction of the section to which it belongs may be; and the curvatures of the sections perpendicular to each other will either cooperate with, or counteract each other, accordingly as the convexities of both are on the same side, or on the opposite sides, of the surface. But the simple consideration of the tension, supporting the weight of the parts below, or the equivalent pressure in a contrary direction, will at once afford us the equations necessary for the solution of the problem, without any immediate reference to the curvature in question.

D. The form of a surface of revolution may be determined by means of an infinite series.

The fluxion of the weight or mass of the parts, contained within the cylindrical surface, of which x is the radius or absciss, and y the ordinate, being always proportional to ydx , and the fluent to $\int ydx$; and the extent of the circumference supporting it varying also as x , and the contractile force being diminished, when reduced to the direction of gravitation, in the ratio of the radius unity to the sine of the elevation s , it will always be proportional to xs ; so that we have the general equation $\int ydx = mxs$. Now if we suppose y incomparably greater than x , and the surface extremely minute, the variation of y may be neglected, and we have in this case $\int ydx = \frac{1}{2}yx^2$: and supposing also $s = 1$, and the curve vertical, $\frac{1}{2}yx^2 = mx$, and $\frac{1}{2}yx = m$; x becoming also equal to the radius of curvature: but it is easy to perceive that the height y must be twice as great, for any value of x , as in the case of a simple curvature, since each portion of the circumference has here only to support a wedge, which is only half as heavy as a parallelepiped of the same height; so that $\frac{1}{2}yx$ will be equal to yx in Proposition A, and $m = r$.

In order to obtain a series for finding y , from the equation $\int ydx = mxs$, we may put the tangent

$$t = \frac{dy}{dx} = bx + cx^3 + dx^5 + \dots, \text{ whence } y = a +$$

$$\frac{1}{2}bx^2 + \frac{1}{4}cx^4 + \frac{1}{6}dx^6 + \dots, \text{ and } \int ydx = \frac{1}{2}ax^2 +$$

$$\frac{1}{2.4}bx^4 + \frac{1}{4.6}cx^6 + \frac{1}{6.8}dx^8 + \dots; \text{ and the value}$$

$$\text{of } s = \frac{t}{\sqrt{1+t^2}} \text{ being expanded into a series, as in}$$

$$\text{Proposition C. n 6, calling } \frac{1}{m}, \text{ or } \frac{1}{r}, q, \text{ we find } s =$$

$$\frac{q}{x} \int ydx = bx + cx^3 + dx^5 + ex^7 + \dots$$

$$-\frac{1}{2}b^3x^3 - \frac{1}{2} \cdot 3b^2cx^5 - \frac{1}{2} \left\{ \frac{3b^2d}{3bc^2} + \right\} x^7 + \dots$$

$$+ \frac{5}{8}b^5x^5 + \frac{5}{8} \cdot 5b^4cx^7 + \dots$$

$$- \frac{1}{15}b^7x^7 - \dots$$

$$= \frac{1}{2}qax + \frac{1}{2.4}qb^3x^3 + \frac{1}{4.6}qcx^5 + \frac{1}{6.8}qdx^7 + \dots;$$

$$\text{consequently } b = \frac{1}{2}qa = \frac{a}{2r}, \text{ and } a = \frac{2b}{q} = 2rb, \text{ and}$$

Cohesion by continuing the calculation and reducing the values, we find

$$c = \frac{1}{2.4} q b + \frac{1}{1} b^2$$

$$d = \frac{1}{2.4^2.6} q^2 b + \frac{10}{2.4.6} q b^2 + \frac{3}{2.4} b^3$$

$$e = \frac{1}{2.4^2.6.8} q^3 b + \frac{82}{2.4.6^2.8} q^2 b^2 + \frac{105}{2.4.6.8} q b^3 + \frac{15}{2.4.6} b^4$$

$$f = \frac{1}{2.4^2.6^2.8^2.10} q^4 b + \frac{652}{2.4.6^2.8^2.10} q^3 b^2 + \frac{2645}{2.4.6.8^2.10} q^2 b^3 + \frac{1260}{2.4.6.8.10} q b^4 + \frac{105}{2.4.6.8} b^5$$

$$g = \frac{1}{2.4^2.6^2.8^2.10^2.12} q^5 b + \frac{5197}{2.4.6^2.8.10^2.12} q^4 b^2 + \frac{59855}{2.4.6.8.10^2.12} q^3 b^3 + \frac{70522.5}{2.4.6.8.10.12} q^2 b^4 + \frac{17325}{2.4.6.8.10.12} q b^5 + \frac{945}{2.4.6.8.10} b^6$$

$$h = \frac{1}{2.4^2.6^2.8^2.10^2.12^2.14} q^6 b + \frac{41800}{2.4.6^2.8^2.10^2.12^2.14} q^5 b^2 + \frac{1303034}{2.4.6.8^2.10^2.12^2.14} q^4 b^3 + \dots$$

$$i = \frac{1}{2.4^2.6^2.8^2.10^2.12^2.14^2.16} q^7 b + \frac{839412}{2.4.6^2.8^2.10^2.12^2.16} q^6 b^2 + \dots$$

$$k = \frac{1}{2.4^2.6^2.8^2.10^2.12^2.14^2.16^2.18} q^8 b + \frac{2779888}{2.4.6^2.8^2.10^2.12^2.16^2.18} q^7 b^2 + \dots$$

$$l = \frac{1}{2.4^2.6^2.8^2.10^2.12^2.14^2.16^2.18^2.20} q^9 b + \frac{22941328}{2.4.6^2.8^2.10^2.12^2.16^2.18^2.20} q^8 b^2 + \dots$$

We may here observe, that the numerical coefficients of the highest powers of b form the series $\frac{1}{2}$,

$\frac{3}{2.4}, \frac{3.5}{2.4.6}, \frac{3.5.7}{2.4.6.8}, \frac{6}{6}, \frac{3.5.7.9}{2.4.6.8.10}, \frac{8}{6}$, the ratio of the

successive terms of both continually approaching to equality, and those of the next in order the

series $\frac{3}{2.4}, \frac{2}{6}, \frac{3.5}{2.4.6}, \frac{4}{6}, \frac{3.5.7}{2.4.6.8}$: but the laws of the

numerical coefficients in general appear to be wholly incapable of being reduced to any simple form. It will be convenient for calculation to form tables of the logarithmic values of these coefficients, which may be continued, by means of successive differences, for as many terms as are requisite for any practical purpose. The indices, with lines drawn over them, are to be considered as negative numbers.

Cohesion. E. The elevation or depression of a liquid contained in a given tube may be found by reversing the series.

Having a given value of x , the semidiameter of the tube, and also of s , the elevation or depression of the surface of the liquid at the point of contact with the solid, we obtain an equation of the form $s = Ab + Bb^3 + Cb^5 + \dots$, and from this we may determine the central elevation or depression $a = 2rb$ by the well known method of the reversion of series, which give us the value $b = \frac{1}{A} s - \frac{B}{A^3} s^3 +$

$$\left(\frac{C}{A^5} - \frac{3B^2}{A^4} \right) s^5 - \left(\frac{D}{A^7} - \frac{sB^3}{A^5} + \frac{12B^2}{A^{10}} \right) s^7 - \dots$$

But it is more convenient to assume an approximate

value of b , a little less than $\frac{s}{A}$, and to find the corresponding value of s ; then since $ds = Adb +$

$Bb^2db + 5Cb^4db + \dots$, if we make $Ab +$

$3Bb^3 + 5Cb^5 + \dots = z$, we shall have $\frac{ds}{db} = \frac{z}{b}$;

consequently the small increments of s and b will be to each other as z to b , and we obtain the correction of b from the error of the calculated value of s : and if the calculation be repeated with the corrected value of b , the second result will always be sufficiently near to the truth.

In order to judge of the accuracy of this mode of calculation, which Mr Laplace appears to have thought liable to some undefined objection, it will be necessary to enter into the details of its different elements, which will sufficiently show the degree of convergence of the series, and the greatest possible amount of error.

Values of the Coefficients of s for Tubes of different Diameters, r being .005, and $s = .75$.

14.004	.7449 + .0040 + .0008 + .0002 + [.0001]

It appears upon inspection of this table, that the coefficients of bx alone always determine $\frac{2}{3}$ of the value of the quantity required, and these are easily calculated with perfect accuracy, so that the error must always be far less than $\frac{1}{100}$, and in fact the actual uncertainty never exceeds $\frac{1}{1000}$ of the whole, at least in the last four examples. The differences of Mr Laplace's approximatory calculations from these results are incomparably greater, so that we cannot hesitate to consider these differences as er-

rors. Indeed, when we recollect that in the method employed by Mr Bouvard, under Mr Laplace's directions, the radius of curvature of each of the small portions, into which the curve has been cut up, has been determined from the ordinate at the beginning of the portion, it is obvious that the curvature thus found must be less than the truth, and that in order to obtain any required curvature of the whole surface, the depression must be increased in the same proportion: and there is no ready way of appreciating the amount of this error. Dr Young had before attempted to avoid it, in making an estimate of the same nature, by calculating for the middle of each portion; but from some accident, the numbers of his table, published in 1807, are generally a little too small, although the method, which he then employed, is nearly the same as that which Mr Laplace afterwards adopted; except that for the lowest portion of the curve, Mr Laplace had recourse to an infinite series, applicable only to that part. The elements deduced in Nicholson's journal for 1809, from Mr Gay Lussac's experiments, which are $r = .0051$ and $s = .7353$, agree better with the numbers found in Mr Laplace's table, than those from which it was constructed, which were $r = .005038$ and $s = .729$; the depressions being always a little larger than the true results from the elements assumed.

The value of the ordinate y depends also principally on the first variable member of the series, although the subsequent coefficients are not so inconsiderable as in the determination of the sine. Thus taking $x = .2$, and $b = 1.503$, we have $y = a + .813bx^2 + .99b^3x^4 + 2.97b^5x^6 + \dots = .01503 + .0489 + .0054 + .0015 + [.0006] = .0714$, which is the marginal depression, leaving .0564 for the height of the convex portion $y - a$. We may determine the effect of any small variations in this height, in the same manner as that of the sine of the inclination: supposing them to depend on a change of the angle of contact only, the quantity r remaining unaltered, it is obvious that q and x must retain their value, while y and b only vary; and making

$$Y = Ab + 3Bb^3 + \dots = b \frac{d(y-a)}{db}, \text{ we have } Y : b$$

$= d(y-a) : db$. In the present instance, we find $Y = .0489 + 3 \times .0054 + 5 \times .0015 + \dots = .079$; and supposing, as in the example suggested by Mr Laplace, the variation of the height $y - a$ to be .00394, which is $\frac{1}{20}$ of Y , that of b will be $\frac{1}{20}$ of b , or .075, and the variation of the central depression a , .00075, which is somewhat less than one fifth of the alteration in the height of the convex portion: but in smaller tubes it is obvious that the variations of the depression a might much exceed that of the height of the convex portion. Nothing can be easier or more direct than this part of the calculation; and it is remarkable that Mr Laplace should have considered the awkward contrivance of building up a curve, like the arch of a bridge, with fourteen blocks on each side, as possessing any thing like an "advantage" over the series in the determination of this variation.

If we wish to find the effect of a small variation of the diameter of a tube, from D to $D \pm D'$, on the depression a of the mercury contained in it, we may

Cohesion.

Cohesion
||
Coinage.

use for the interpolation the formula $\frac{a'}{a} = 10^{CD' - 1}$,

C being about 2.9 for tubes between 1 inch and $\frac{1}{4}$ th of an inch in diameter, and being elsewhere easily deduced from the depressions already known. For variations of the cohesive power, and of its measure r , we may suppose the whole of the numbers of the table to be altered in the proportion of the supposed alteration of \sqrt{r} , and the change produced by restoring the diameter to its former dimensions may then be calculated like any other interpolation. There is also a more comprehensive formula, which seems to express the depression in tubes of all sizes with great accuracy; it is this, $a = \frac{.015}{D + 48 D^{3.492 + .36 D}}$

and it might even be possible to shorten the original calculation by a comparison of the series with the expansion of this empirical formula, if it were of any further importance to facilitate the mode of computation. But for all practical purposes, it will be sufficient to collect the results already obtained into a comparative table, arranged in chronological order: and it is remarkable, that they are so comprehended, without any material exception, between the two values assigned to each as near the truth in Dr Young's first table, the mean of those values never differing a thousandth of an inch from the result of the more correct calculation; while the error of Lord Charles Cavendish's experiments, notwithstanding their general accuracy, sometimes amounts to nearly one hundredth.

(F. O.)

COINAGE.

UNDER this head it will be proper to give a brief account of the constitution of the Royal Mint, as well as of the different processes which come under the general term *Coinage*; for all these processes are conducted under various checks emanating from the constitution which the legislature has thought proper to give this Royal Establishment.

The Royal Mint attained its constitution of superior officers in the 18th year of the reign of Edward II., and, with very few alterations, continued as then established till the year 1755. Of the alterations in this latter year we shall have occasion to speak hereafter.

Edward appointed a Master, Warden, and Comptroller, King's and Master's Assay Master, and King's Clerk, besides several inferior officers, whose duties will be mentioned hereafter. Previous to this period, we have very little information as to the system of coinage pursued at the various mints which the kings

of England had throughout their dominions. The Rev. Roger Hudding, in his valuable and laborious *Annals of the Coinage of Britain and its Dependencies*, gives it as his opinion, that the moneyers were in very early ages the only officers employed in the fabrication of the money. On the early Anglo-Saxon coins are found, besides the names of the monarchs, those of other persons, who are with great probability conjectured to have been the moneyers, because on the later Anglo-Saxon money the names of those officers frequently occur, with the addition of their title of office. From the circumstance of their names being inscribed on the coins, it is reasonable to conclude, that they were responsible for the integrity of the money, and that likewise they were the principal officers of the mint, because inferior officers would have given security to their superiors, whose names would have appeared on the money, as a pledge to the sovereign that it

Chief Es-
tablishment
of the Mint.

Coinage. was duly executed. The silence also of the Anglo-Saxon laws, and of *Doomsday Book*, as to other officers of the mint, whilst they so frequently mention the moneyers, greatly corroborates the opinion, that they were the only persons employed in the Anglo-Saxon and early Anglo-Norman mints, except, perhaps, occasional labourers; and it is observable, that, when in the reign of Henry I. the money was so much corrupted as to call for a sentence of the most exemplary severity on the offenders, the punishment is said to have been inflicted upon moneyers only, without the least notice of any other officer. This was also the case upon a similar occasion in the reign of Henry II.

Mr Rudding is unable to determine the exact period when it became necessary to place some permanent superintending authority in the mint to prevent the bad practices of the moneyers; but it is probable, he says, that such an officer was appointed between the 26th of Henry II., when the moneyers alone were punished for the adulteration of the money, and the 3d of Richard I., when Henry de Cornhill accounted for the profits of the cambium of all England, except Winchester.

It is not improbable that this first warden of the mint was appointed for the purpose of collecting the revenue arising from the seignorage charged upon coinage of bullion.

The object of the warden's appointment might also extend to the inspection of the fabrication of the money, with a view to prevent the master and his moneyers, or the moneyers alone, from taking any undue advantage of the king, or the public, by the adulteration of the coin. The most important officer, however, upon the establishment of the mint, with a view to the maintenance of the standard purity of the coin, is the king's assay master: and there are persons mentioned as holding this office in the 6th of Henry III. As this officer had the assaying of all the bullion after melting for coinage, and after it was coined, it is obvious that the very existence of the credit and honour of the mint and sovereign depended upon the duties he had to perform; and such an officer probably existed from the earliest period of the fabrication of money, though our records do not accurately define the precise date of his appointment.

The next officer of importance in the mint is the comptroller; and the first whom Mr Rudding's researches have discovered, held the office between 5th and 15th of Edward II. His duty, distinct from that of the other officers of the mint, is to make out annually a roll, called usually the comptroll or comptrollment roll, containing an account of all the gold and silver coined, and to deliver it on oath before one of the Barons of the Exchequer. It is always written upon parchment, and forms a permanent record of the coinages of the mint.

The king's clerk and clerk of the papers is the next check officer upon the establishment; as king's clerk, he acts as a check upon the whole process of the coinage, the same as the warden and comptroller; as clerk of the papers, he keeps a book of record of the transactions of the mint. Of the creation of this office we have not been able to find any record.

These are the principal check officers of the mint,

Coinage. and, no doubt, were appointed as mutual checks upon each other's integrity, and to watch over the interests of the king and other importers, of bullion into the mint.

There is another officer upon the establishment, whose duties are important, but of whose origin and appointment we have not been able to find any notice. His title is, the master's assay master, and his duty consists in assaying every ingot of gold and silver brought to the mint for coinage; and upon his integrity the master and worker relies that no bullion shall be received into the office for coinage, but what is conformable to the standard of the realm.

Mr Rudding remarks, Vol. III. p. 1. that, at a very early period of the history of Britain, when the communication between its different parts was extremely imperfect, it became necessary to establish mints and exchanges, not only in the chief city, but also in various other places, for the purpose of supplying the neighbouring districts with money to carry on their commerce. To this necessity alone such establishments are to be ascribed; and accordingly we find that, by degrees, as the communication opened, the subordinate mints and exchanges sunk into disuse, and one fixed in the metropolis was found to be amply sufficient for the supply of the whole kingdom.

Athelstan appears to have been the first monarch who enacted any regulations for the government of the mints. In his laws, which were promulgated about the year 928, he provided that one sort of coin only should be current throughout the kingdom, and granted to various towns, by name, a number of moneyers proportionate to their size and consequence, and to all boroughs of inferior rank one moneyer each.

These mints were under the control of that within the Tower of London, from which, as paramount, the dies were issued; and for which the moneyers paid a regular fee upon every alteration of the coins. They also paid an annual rent, which, in the city of Lincoln, amounted to L.75 (according to the statement of *Doomsday Book*), a very considerable sum at that time. The rents of the other mints were, however, much inferior to this.

To increase the facility of distributing the coins made at these mints, Exchanges were appointed in various places from whence the new coins were issued, and in which bullion was purchased for the supply of the mint; and it appears that our monarchs claimed the exclusive privilege of purchasing bullion, and appointed proper officers, to whom they delegated that branch of their prerogative.

It appears to have been the duty of these officers, not only to exchange the current coins of one metal for those of another, but also to receive wrought plate and bullion, and foreign coins, according to their fineness respectively; and as the exportation of the coins of the realm was prohibited, they furnished persons going out of the kingdom with foreign coins, in exchange for English, and also supplied merchants and strangers coming into the kingdom with English coins in exchange for foreign. These exchanges of coin were regulated by a table, which was hung up in the exchanger's office.

This office, it is said, ceased to exist since the reign of

Coinage. Charles I. Henry Earl of Holland was the last keeper of the exchanges between England and Ireland.

Besides the officers mentioned, there was another of great importance in early times, who bore the title of Cuncator. Mr Rudding mentions this officer as being hereditary, and, as far as he had discovered, the only one in the mint that was so. The engravers of the dies seem to have been appointed by him, and to have been under his immediate cognizance. By him they were presented to the Barons of Exchequer, before whom they took the usual oath of office; and it was probably his duty to see that all the dies (as well those which were used in the paramount mint, in the Tower of London, as those which were issued from thence to the subordinate mints) were of the same type. This was no doubt a circumstance of great moment, when so many mints were allowed to be worked in various parts of the kingdom. When these mints were abolished, and the mint in the Tower became the only source from whence coins were derived, the office sunk into disuse. By right of office, this officer claimed the old and broken dies as his fee. An officer of a similar kind exists in the mint at this day, who is called clerk of the irons, whose duty it is to superintend the manufacture of the dies for coinage; but he has no power to appoint the engravers of the dies.

In the early history of the mint, as at present, the master of the mint fabricated the coins at certain charges per pound weight. He had his regular establishment of melters and moneyers, to whom he paid certain rates for melting and making the monies, reserving for himself a certain fee for his trouble and responsibility. For, in all his engagements with the Crown, the master had to bear all waste and charges arising in and out of the coinage of gold and silver. Mr Rudding mentions that, in the 10th of Edward III. the workmen of the mint of London petitioned the king for an increase of their allowance for coinage; alleging that they were at that time at greater expence, and bestowed more labour, in forming the monies, than had been usual in former times, so that they could not maintain and continue such expence and labour, unless their allowance was increased.

The king being willing to grant their petition if just, commanded John de Wyndesore, warden of the mints of London and Canterbury, together with Lapone Roger, and others experienced in such matters, to inquire whether the allowance was sufficient; and if not, to determine what addition should be made; and they were ordered to make their report in Chancery, under their seals, without delay.

A warrant was in consequence issued, and Lapone and Roger Rikeman, exchangers of London, and Stephen Boke, having been examined on oath by the warden, the following report was made: That, having inquired diligently respecting the necessary expences of the master of the mint and the workmen, viz. of alloy, clay, and salt, and other things used in the making of new money, and also of the expences occasioned by the waste arising from the whitening of the halfpennies and farthings, on account of the increase of the alloy, and from the hardening of the metal of the said coins in work-

ing and coining—they were of opinion that the work could not be carried on without an increase of 3d. for each pound at the least; and with that the workmen ought reasonably to be contented. Then, whereas of old they received for all costs, colour, &c. for a pound of halfpennies, 7½d., and for a pound of farthings, 9½d., they would receive for the former 10½d., and for the latter 12½d., so that the master should have of increase 2d., and the workmen 1d.

It was the duty of the warden to take an account of all the bullion of gold and silver entrusted to the master and worker of the mint to be coined; and in this duty he was aided by the comptroller and king's clerk, who in their respective capacities kept books of entries of the receipt of bullion, and its delivery in coin to those who brought the bullion for that purpose. Besides those duties, these check officers had the superintendence of the different processes through which the bullion had to pass, from the assay of the ingot to the delivery of the coin to the importers; and it is more than probable, that in the infancy of the mint, and when the demand for coin was very limited, the whole processes of the coinage were conducted in one apartment; that the master, warden, comptroller, and other principal officers of the mint, accompanied the sovereign from place to place in his dominions, and actually superintended the fabrication of the coin at the mints of the towns where he sojourned. The progressive civilization of the country, the increasing demand for money, and the more permanent residence of the monarchs in London, gave the mint of the Tower a predominancy over all others; and these circumstances very probably called for the appointment of other check officers, who are now upon the mint establishment; such as the surveyor of the meltings, whose duties are to superintend the melting of the pots of gold and silver, and to weigh the proportion of fine gold or alloy which may be necessary to produce the standard of the money; to take samples of all pots melted, and take them to the king's assay-master, for him to ascertain if the standard has been adhered to by the melter; and to lock up the said pots, of which samples have been taken, in the melter's strong-hold, of which he has one key, and the melter another, and there to retain them until the king's assay-master has declared that they are of the proper standard. In the infancy of the mint, the duties of this officer were probably performed in the presence of the warden, comptroller, and king's clerk; but the increase of duties in the mint office, in the receipt of bullion and delivering coin, probably rendered it necessary to relieve the principal officers from these duties, as well as from those of another office, called the surveyor of the money-presses, whose duties consist in seeing that good dies are used, and clean money made in the coining room.

When these and other officers were in full power, operating as checks upon the coinage, and, consequently, upon the master and worker, they received their salary and fees from the warden, as chief of the check branch of the establishment.

The expenditure for the repairs of buildings, offi-

Coinage. cers' houses, &c. &c. was also paid by the warden of the mint; and his authority for doing so was by the mint indenture, in which these duties are detailed. "And our said Sovereign Lord the King doth will and command, that the warden or wardens of the mint, for the time being, shall content and pay to the officers and ministers aforesaid, such stipends and wages, and such diet, as in schedule limited and appointed, in manner and form, and during such term as in the same expressed; and that thereof he and they shall have due allowance and defalcation upon his or their accounts. And that the said warden or wardens shall make his or their accounts yearly, as well of all and every of his or their receipts, as of his or their payments, and other charges, before the auditors of the mint for the time being, unless it shall please his Majesty otherwise to appoint the same; in which account the same auditors, or others to be appointed by his said Majesty to take the said accounts, shall make unto the said warden or wardens full allowance, defalcation, and discharge, as well for all such sum and sums of money as he or they shall duly prove to have been paid or disbursed for officers' fees and wages, and diet for the said officers, as for any other necessary charges to be employed in and about the making of the said monies, or the repairing of the said offices and houses, necessarily to be employed in the said service, under the avouchment of the said master and comptroller and assay-master, or any two of them, whereof the said master is to be one; and the said accounts so to be made by the said auditors, or by any other of his Majesty's special appointment for the same, being stated, and his debts determined, and his said accounts fully answered to his Majesty, the said warden or wardens, upon his or their suit to the Lord Chancellor, or Lord Keeper of the Great Seal, or Commissioners of the Great Seal, shall have letters patent of his said Majesty under the great seal, to be made on his or their acquittance, without fee therefor paying; for the making of which said letters patent, these presents shall be a sufficient warrant and discharge to the said Lord Chancellor, or Lord Keeper, or Lords Commissioners for the custody of the Great Seal, for the time being, without any further or special warrant to be sued out for the same."

Notwithstanding the number of the checks upon the coinage of our money, its history gives us the most undeniable proofs of their inefficiency, when the arbitrary will of the sovereign was allowed to put all law and justice aside. However much we may admire the precautions used by our ancestors in the formation of the constitution of the mint, we have still the painful recollection (though its forms and regulations have existed since the reign of Edward III.) that they could not prevent a Henry VIII. from disgracing his reign by, perhaps, the most wanton debasement of the currency, that was ever, in a similar period of time, practised in any country in the world. The same ignorance and injustice disgraced the beginning of the reign of his son, Edward VI., but the subsequent acts, even of his short reign, were a good apology for the impolicy of his measures, and the severest censure upon the injustice of his father's acts regarding the currency. The

VOL. III. PART I.

short reign of Edward VI. prevented that thorough reformation in the currency which the wisdom of his measures began, and which was perfected in the long and glorious reign of his successor, Elizabeth.

In the early history of our coinage, its expences were paid by a duty or seignorage upon the money coined; and, besides these expences, a certain duty was retained for the sovereign, and was one of the sources of his revenue. The amount of this duty was regulated entirely by the will of the sovereign, and without any regard to the principle by which it was assessed; it varied in different reigns, and was probably, in a great measure, regulated by the necessities of the sovereign for the time being. The mere charge of coinage, as Mr Radding justly remarks, is probably as ancient as the invention of coined money; because it would soon be discovered, that the sovereign, after having turned his bullion into coins, for the benefit of his subjects, was no richer than before. It is probable, however, that the deduction did not remain long at the simple expence of coinage, but was soon made a profitable and easily collected source of revenue. In fact, the prerogative of coinage being exclusively the sovereign's, made it a certain source of revenue. In the earliest mint accounts which Mr Radding has met with, viz. one of the 6th of Henry III., the profit upon the coinage was 6d. in the pound. This appears, says Mr Radding, from the entries, under that year, of bullion coined in the mint at Canterbury, when the profit upon L. 3898, 4d. is stated to be L. 97, 9s., which is exactly 6d. in the pound. Of that sum the king had L. 60, 18s. 3½d., and the archbishop L. 36, 10s. 10½d. (these totals do not precisely agree, as is frequently the case when sums are stated in Roman numerals); the whole sum of L. 97, 9s. is stated to be the amount of *exitas lucri*, that is, we presume, the clear profit, after all the expences were deducted. And this will agree with the seignorage which was taken in the 28th year of Edward I., amounting to 1s. 2½d. upon every pound, out of which the master had 5½d. for all expences, and there remained 9d. clear profit to the king.

As this latter date is about seventy-eight years subsequent to the former, it is not improbable that the seignorage had been raised in that time, in the proportion of nine to six.

A seignorage continued to be charged upon the coinage of both gold and silver until the reign of Charles II., who, after his restoration, took the expences of the coinage of the money of the Commonwealth upon himself. Regulations introduced by Charles II.

In September 1661, in the 13th year of his reign, a proclamation was issued, declaring, that the gold and silver coined during the period of the Commonwealth should not be current after the last day of November in the same year. At the same time it declared, "that such of our subjects in whose hands these moneys shall be found after the last day of November next ensuing, may not suffer too great damage or prejudice thereby, we are pleased further to declare, that all and every person and persons who shall bring any gold or silver coyn of the stamps and inscriptions aforesaid into our mint in the Tower of London, shall there receive

F f

Coinage.

the like quantity of lawful and current moneys, weight for weight, allowing only for the coinage."

On the 7th day of December in the same year, another proclamation was issued, declaring the money of the Commonwealth current only in payment of taxes, &c. to his Majesty, and to continue so to the 1st day of May next ensuing. The object of this proclamation was to bring as much of this money into his Majesty's exchequer as possible, for the purpose of recoinning it. It is in this proclamation that the king takes the expence of coinage upon himself: "We being willing," it says, "for the ease of our subjects, to take the charge of the coinage thereof upon ourself."

It was in these proclamations that the system began of charging the government with the expences of the coinage of this country. The merchants and others, who were interested in saving both the duty and the expence of coinage, took advantage of the last mentioned proclamation, and represented to the king and his council by memorials, the great advantage which trade and the country at large would derive from the sovereign taking upon himself, as a permanent charge, the expence of coinage; they also represented that a great increase would take place in the quantity of money, if coined free of any charge to the importers of bullion. As these representations were irreconcilable with the just principles of public wealth,—as they were brought forward by persons ignorant of the consequences which would attend their execution, we much doubt whether they produced the effect which the interested individuals were so desirous of obtaining. In the 18th year of the same reign, an act was passed, exempting, in future, the importers of bullion from all charge of coinage, and which has continued till the present day.

As the science of political economy was very little understood in the period here mentioned, it is not to be wondered at, that the voices of a few interested individuals could procure the passing of an act so plausible. There can be no doubt but Charles and his council were swayed by the apparent knowledge which those individuals evinced in the practical details of business, and trusted to their representations being correct; but a practical knowledge of business, founded upon mistaken principles, must lead to erroneous conclusions; and it is easy to prove, that Charles and his council were imposed upon by these practical men.

This country would, at least, have been equally rich, and the quantity of coined money in no degree diminished, if the charge of workmanship had been continued upon the coinage; for the quantity of money in a country that possesses no mines of its own, must be regulated by the produce of its land and labour,—upon the quantity of exchangeable commodities; and as the quantity of exchangeable commodities increased, so would the quantity of money be increased, except in so far as good husbandry, or increased value of the precious metals could make it be spared to circulate them. As the charge of coinage could have no effect in diminishing the quantity of the precious metals that would be imported into the country; the portion of this bullion, that would be brought to the mint to be coined,

would depend upon the demand for coin; and this demand would regulate the profits, which the individuals, who did coin, could make by it, either in trading with it themselves, or by lending it to others.

If there were a charge for coinage, there would, strictly speaking, be a less quantity of bullion imported, because we should have a less quantity of money than we now have; but that money would be more valuable. A guinea or 5 dwts. $9\frac{1}{2}$ grs. would be more valuable than 3 dwts. $9\frac{1}{2}$ grs. of gold bullion, and consequently fewer of them would be requisite for the circulation of the same amount of commodities. The effect would, therefore, be to increase the quantity of commodities, and to lessen the quantity of bullion or coin.

The policy of Charles's measures with respect to the coinage, have been questioned by various writers. And, in fact, the principle of a seignorage, so often agitated, has never been satisfactorily settled. Lord Liverpool, in his excellent *Letter to the King upon the Coins of the Realm*, conceives that a seignorage upon our gold coin, which is the standard money of our country, would necessarily cause that measure of property to be imperfect. His Lordship has not favoured us with any account of the nature of the imperfection that would have been created by charging a seignorage upon our gold coins. The only imperfection that could be called into existence we apprehend, by charging the expence of coinage upon gold, would be the alteration which it would make in its value. L. 100 of gold coin, chargeable with an expence of coinage (say of $1\frac{1}{2}$ per cent.), would, while the king preserved the monopoly of coinage, be more valuable than its weight of uncoined gold; and consequently would alter the state of debtor and creditor, as well as require the Government to pay her annuitants, and other branches of her expenditure, in a currency more valuable than before the charge of seignorage was imposed.

Let us, for example, suppose that we had only coins of gold in this country, and that a seignorage to the amount of the expences incurred in their manufacture was imposed by the legislature, say of $1\frac{1}{2}$ per cent., it must be evident that a L. 100 of such coins would be more valuable than their weight in bullion of the same purity, by the expence of the coinage. Every L. 100 of such gold currency, therefore, would purchase not only its weight of bullion, but $1\frac{1}{2}$ per cent. more, as the expence of converting such bullion into coin. As no legal coin can be obtained but where this charge is made, the market-price of gold would thus be $1\frac{1}{2}$ per cent. under its mint price. If the seignorage exceeded the expences of the coinage, so as to afford a profit to the illegal coiner, supposing him to coin money of the legal standard in weight and fineness, then would the value of the currency be reduced by such illegal additions to its quantity; the market price of bullion would approach to its mint price, but would fall short of it by the real expences of the coinage, and would thus destroy the profits of the illegal coiner. It will also follow, that a L. 100 of such currency would purchase a greater quantity of any commodity than its weight of bullion of the same purity

Coinage.

Question as to the effects of a Seignorage.

Coinage. would do, and that by the expences of the coinage, or $1\frac{1}{2}$ per cent. By the imposition of a seignorage, therefore, the price of bullion and commodities would experience a fall, limited however by the real expences of the coinage, no laws having yet been devised to prevent illegal additions to the currency. We should not however apprehend that the coins fabricated under this system would in any degree be imperfect: on the contrary, we think that a considerable national advantage might have been the result, had such a principle been adopted at the British mint. As the value of the coins would be increased, so would their quantity have been diminished. A smaller amount of currency would have circulated the same quantity of commodities. The gold thus relieved from the channel of circulation, would, in the hands of individuals, have become capital, the nation deriving all the advantages of its reproduction, with a profit.

The second objection of Lord Liverpool, if well-founded, would certainly render it impolitic in the legislature to enact a seignorage upon the coins constituting the principal measure of property, either as a present or primary principle in the government of the mint. "The merchants of foreign nations, who may have any commercial intercourse with this country, estimate the value of our coins only according to the intrinsic value of the metal that is in them; so that the British merchant would, in such case, be forced to pay in his exchanges, a compensation for any defect which might be in these coins; and he must necessarily either raise the price of all merchandise and manufactures sold to foreign nations in proportion, or submit to this loss."

If the imposition of a seignorage had no effect in augmenting the value of the coins, Lord Liverpool's objection would be correct; but we have already stated, that the coins acquire a value proportionate to the expence of the coinage; the natural limit of a seignorage where the laws cannot prevent illegal additions to the amount of the currency. If so, the relation between the foreign and British merchant would in no degree be changed; they would continue to buy and sell, with the same advantages as before the seignorage was imposed:—there would, it is true, be some differences in price, but not to affect the relative interests of the parties. For example, if a seignorage of $1\frac{1}{2}$ per cent. was imposed upon the currency of England, while that of Hamburg remained without alteration, it will be evident, from what has already been stated, that a fall in the price of British commodities would take place in consequence; but this fall in prices would not be confined to British commodities alone; the foreign commodities brought to the English market must necessarily undergo the same reduction; but the foreign merchant would not be subject to any loss in consequence of this fall in the price of his commodities; for the reduction in the price of English goods enables him to buy as much cheaper as will compensate for the diminution in the price of his foreign wares: neither would the British merchant be subject to any loss by the fall in prices, he being enabled to buy foreign commodities so much cheaper as to compensate for the reduction in the price of English commodities.

Coinage. The exchanges with foreign nations would be regulated by the same principle. A merchant in London, for example, wanting to remit L. 100 to his correspondent in Hamburg, to discharge a debt which he owed there, would with his L. 100 of English currency, augmented of $1\frac{1}{2}$ per cent. in value by a seignorage, buy upon the London Exchange a bill upon Hamburg, entitling him to a quantity of Hamburg currency equal in value to L. 101, 10s.—thus would bills upon Hamburg be said in the London market to be at a discount $1\frac{1}{2}$ per cent. But England would not gain by this discount upon Hamburg bills; for, if we suppose that a merchant in Hamburg wishes to discharge a debt in London of L. 100, all bills on London, sold in Hamburg, will, upon the same principle, be sold at a premium equal to the increased value of the currency in England, to which these bills entitle the holders of them.

As a nation cannot permanently import to a greater amount than it exports, the holders of bills in London upon Hamburg, cannot permanently exceed the holders of the bills in Hamburg upon London, so that the discount on Hamburg bills in the one case, and the premium on London bills in the other, will necessarily balance each other; so that neither party, if we are correct in our argument, would lose or gain, as far as related to the exchange by the imposition of a seignorage upon the British currency.

The third objection of Lord Liverpool to a seignorage upon the gold currency of England is, "That no such charge of fabrication has taken place at the British mint for nearly a century and a half past; and, if it were now to be taken, the weight of the new gold coins must be diminished to pay for this fabrication."

It does not necessarily follow, that a charge for the fabrication of our gold coins should diminish their weight to pay for such fabrication. If the expence of coining L. 100 of gold currency at the Royal Mint was L. 1, 10s., the individual bringing the bullion to the mint, having this charge to defray, would not sell his L. 100 in coin for its weight in bullion; the value of the coin being augmented by the value of the workmanship, he would readily command a quantity of gold bullion more than its weight by the expence of the coinage, or $1\frac{1}{2}$ per cent., as has been already stated. This mode would render any change in the weight of the coin unnecessary.

Lord Liverpool's last objection is, "That these new gold coins would either differ in weight from those now in currency, or, to prevent this evil, the whole of our present gold coins must be taken out of circulation, brought to the mint, and be recoinced."

If we are correct in our answer to his Lordship's third objection, the last one will necessarily fall to the ground. All the advantages of a seignorage may be obtained, without such seignorage being deducted from the weight of the coins.

From the arguments we have adduced, we should be justified, we apprehend, in approving of the principle of a seignorage, even upon the coins which constitute the principal measure of property, provided it did not exceed the mere expence of the coinage of such coins; for where a seignorage is charged, there is a tendency, as we have already

Coinage.

noticed, to a fluctuation in the value of that currency,—an evil which should be avoided as much as possible. Where an extensive paper currency is used, as in England, this evil is considerably increased, even though the issuers of it are liable to pay it in specie on the demand of the holders; still both their notes and the coin might be depreciated to the full extent of the seignorage, before the check which limits the circulation of paper could operate. If the seignorage on our gold coin were 5 per cent., for example, the currency, by an abundant issue of bank-notes, might be really depreciated 5 per cent. before it would be the interest of the holders to demand coin for the purpose of melting it into bullion,—the legal check to restore it to its proper value. If the seignorage amounted only to the mere expence of coinage, which is about 10s. per cent., that would be the whole fluctuation in the value of our legal currency, even though bank notes, payable on demand, formed the most considerable portion of it.

When Charles II. annulled the law for charging a seignorage upon our coins, he must have caused that alteration in the value of property which we here state as the *reason* why we cannot recur to it again, consistently with our national honour. And the late act respecting coinage, which allows a seignorage to be charged upon silver of 4d. per oz., but which directs that no charge whatever should be made on gold, it being the standard of property, is therefore a wise measure; as it preserves the integrity of that standard which has existed for upwards of a century, and by which the value of all property has been regulated.

If a seignorage, therefore, is ever charged, it should be from the first introduction of coined money in a state, and ought never to fluctuate in amount, as was anciently the case in this country; because such fluctuations must cause as frequent fluctuations in the value of property, an evil which cannot be too carefully avoided.

Improvements in the Machinery during the Reign of Charles II.

The next important event in the history of the mint, was the introduction of the mill and screw, which took place soon after the restoration of Charles II. Previous to his reign, the money in circulation was made by forging or hammering slips of gold and silver to the proper degree of thickness, then cutting a square from the slip, which was afterwards rounded and adjusted to the weight of the money to be made; the blank pieces of money were then placed between two dies, containing the design of the coin, and the upper one was struck with a hammer. This money was necessarily imperfect, from the difficulty of placing the two dies exactly over each other when the blank piece was between them, as well as from the improbability of a man being able to strike a blow with such force as to make all parts of the impression equally perfect.

The mill or press was first introduced from France into this country in the reign of Queen Elizabeth, but after a few years use was abandoned, as too expensive, and the hammer coinage resumed.

The coining press or mill is of French origin, and is generally ascribed to Antoine Brucher, an engraver, who in 1553 first tried it in the French King's

(Henry II.) palace at Paris, for the coining of counters. It continued in use till 1585, in the reign of Henry III., when it was laid aside, on account of its being also more expensive than the hammer coinage. The machine remained in disuse until 1623, when Briot, a French artist, who was unable to persuade the French government to adopt it again, came to England, where it was immediately put in practice under Briot's direction, who was appointed chief engraver of the mint.

Coinage.

Like many other new inventions, it was sometimes used, then laid aside, and the hammer resumed for about 40 years. In the year 1662, the mill and screw were completely established in the English mint, as it had been by the French in the year 1645. The great improvement which took place in the form and impression of the coins struck by this new invention, gave them a decided superiority over the hammer money; and the excellent and truly philosophical improvements of the late Mr Boulton, which we shall hereafter describe, have placed the process of coining upon a basis so firm, and so decidedly superior, both in facility and economy, that we have no fear of returning to the ancient and less perfect mode of fabricating our money.

The next important feature in the history of our mint, was the extensive silver recoinage of King William, which amounted to upwards of L.7,000,000 Sterling. It was executed at several country mints, besides the mint in the Tower of London. The principle upon which this recoinage was executed, was a subject of great controversy, and occupied the talents of Mr Locke, Mr Lowndes, and others. Mr Lowndes wished to execute the coinage at a rate per oz. conformable to the market price of silver; overlooking, at the same time, that the market price exceeding its mint price, arose from the deficiency in the weight of those coins by which silver, as well as all other commodities, was bought and sold. Mr Locke, with that acuteness for which he was so justly esteemed, contended that, if 5s. 2d. of the coin weighed an oz. that would necessarily be the market price of silver; and that its high price arose from 6s. 4d. of the then currency containing no more than an oz. of standard silver. Consequently, if the coinage was executed at a rate higher than the standard of the 46th of Elizabeth, or 5s. 2d. per oz. it would be done at the expence of that justice and integrity between the government and the people, which no government would sanction that regarded the rights of personal property. Mr Locke's arguments were so decidedly just, and so convincing, that the government carried the whole nation with them in the measure, though it was heavily felt, owing to the exhausted state of the country, after the long and expensive war it had been involved in.

Recoinage of Silver in King William's Reign.

Controversies occasioned by this Recoinage.

In the course of a little time after the recoinage was completed, Mr Locke's reasoning was called in question, from the circumstance of the price of silver exceeding its mint price, and the consequent disappearance of the coinage, by melting the coins into ingots for sale at the high market price. As this is an exceedingly curious and interesting portion of the history of our mint affairs, we may be allowed to

Coinage.

state a few facts by way of vindicating the accuracy of Mr Locke's theory, and to point out the real cause why its application to practice failed, as it is generally acknowledged that it did; the greater portion of the silver recoinage having, before the year 1717, disappeared from the circulation.

By an *Abstract Account* of the prices which the Bank of England paid for gold and silver bullion in each year, from 1697 to 1811, it appears, that, as early as 1710, they paid L. 4 *per oz.* for standard gold, and 5s. 3d. for standard silver; and, it is probable, that the same price existed at a more early date after the recoinage, though the accounts state no price before 1710. This account we conceive of very great importance, and, we think, will satisfactorily explain why Mr Locke's theory did not permanently produce the effect which the legislature expected from it.

By a reference to the prices paid for gold by the Bank of England from 1710 to 1717, it appears, that the average price *per oz.* was L. 3, 19s. 11d. During this period, the guinea was current for 21s. 6d., at which rate the oz. of gold was coined into L. 3, 19s. 8½d.; for, if one guinea or 5 dwts. 9¾ grs. be worth 21s. 6d., 480 grs. or 1 oz. will be worth L. 3, 19s. 8½d. It would appear, then, that the market price of gold was only 2½d. above its mint price; and some debasement by wear may have existed upon the gold currency at this period, causing such excess of the mint price.

While the mint, therefore, coined gold at the rate of L. 3, 19s. 8½d. *per oz.*, and silver at 5s. 2d., the relative proportion was as 15.43 to 1. There is only one quotation of silver given for the period in question, and it is 5s. 3d. *per oz.* If we take this as the average price for the seven years in question (and we may be justified in doing so by the market prices which follow in 1718 and subsequent years, as extracted from Castaign's *Papers*, and laid before the House of Commons, and ordered to be printed 4th March 1811), at 5s. 3d. *per oz.*, the average proportion of gold and silver in the market would be 15.22 to 1. But no individual would carry 15.22 ozs. of silver to the mint to be coined into about L. 3, 18s. 7d. when these 15.22 of silver would procure an ounce of standard gold in the market, which could be coined into L. 3, 19s. 8½d. making thereby a profit of about L. 1, 7s. 6d. *per cent.* While this profit continued, it may reasonably be inferred that gold, and not silver, would be the standard of our money.

It was in September 1717, that Sir Isaac Newton delivered in his *Report* to the Lords of the Treasury, giving it as his opinion, that gold was considerably overrated in the mint with respect to silver; and, in consequence of this report, the guinea was, by proclamation, dated 22d December 1717, declared current at 21s. It is of importance to observe the effect produced upon the price of gold by this proclamation; and we are of opinion it will completely prove, that the silver currency had not operated as the standard of value during the period in question. When the guinea became a legal tender at 21s., the price of gold became fixed at L. 3, 17s. 10½d. *per oz.* at the mint; for, if 5 dwts. 9¾ grs. be worth 21s., 480 grs. or 1 oz. will be worth L. 3, 17s. 10½d. This

Coinage.

fall in the price of gold from L. 3, 19s. 8½d. is 1s. 10½d. *per oz.*, and is equal to about L. 2, 6s. *per cent.* It appears by the abstract of prices paid for bullion by the Bank of England, that in 1718 and subsequent years they paid L. 3, 18s. *per oz.* for standard gold, which is a fall from L. 3, 19s. 8½d. of 1s. 8½d. *per oz.*; and if an allowance is made for the debasement by wear, existing at this period upon the gold coin, the fall in the market price of gold will be equal to the reduction in the value of the guinea. But this effect could not have been produced unless gold at the period in question had been the measure of value, and, as such, the measure of its own price.

From these facts, we think the conclusion may be justified, that from 1710, and probably a more early period after the recoinage, to the date of Sir I. Newton's report, the gold money of this country was the standard measure of property; and that the reduction of the value of the guinea, thereby making the relative proportion of gold and silver approximate nearer to those of the market, was the first step of which we have an authentic record, taken by Government to maintain the principles of Mr Locke's theory: and as the avowed intention of this report was to give that rise in value to the silver coin which would protect it from the melting pot, and which could be done by lowering that of gold, it may be inferred, that the legislature were aware that the gold coin had attained the prerogative of being the standard of value at this time. Though the recommendation in Sir I. Newton's report was carried into effect, by making the guinea current at 21s., yet it did not restore silver to its function as the standard of our money; and this, because the current value was not made still lower. Sir I. Newton seemed aware of this himself, and recommended that 10d. or 12d. should be taken from the guinea instead of 6d. This however was not done; and, as the rate of 21s. to the guinea, the proportion of standard gold to standard silver, at the mint, was as 15.07 to 1, the proportion of the market, as we find by the prices of gold and silver at this period in Castaign's *Papers*, was about 14½d. to 1; which constitutes a difference of about 3 *per cent.*, gold being still thus much rated above its value to silver; and consequently, not only was no silver coined, but the good and heavy coins were still melted for the high price they brought in the state of bullion. It is surprising that the Government, having seen the operation of the principle recommended in the report of Sir I. Newton, did not carry it a little further, and bring the current value of the guinea to a par with the market proportion of the two metals, and so render it the interest of the public to carry silver to the mint to be coined.

Before concluding our observations upon this highly interesting subject, we must remark, that the great Mr Locke himself did not impute the high price of silver, after the recoinage, to the cause to which we have here assigned it. He attributed it to the permission of exporting silver bullion, and to the prohibition of exporting silver coin. This permission, he said, rendered the demand for silver bullion greater than the demand for silver coin. Dr Adam Smith remarks upon this opinion, that the number of

Coinage.

people who want silver coin for the common uses of buying and selling at home, is surely much greater than that of those who want silver bullion, either for the use of exportation, or any other use. There subsists at present a like permission of exporting gold bullion, and a like prohibition of exporting gold coin; and yet the price of gold bullion has fallen below the mint price. But in the English coin, silver was then, in the same manner as now, underrated in proportion to gold; and the gold coin (which at that time was not supposed to require any reformation) regulated then, as well as now, the real value of the whole coin.

No other legislative measure having been taken than what we have mentioned, founded upon the *Report* of Sir I. Newton; and the market proportion of gold to silver having seldom rendered it the interest of the public to coin silver; this accounts satisfactorily for the degraded state of our silver currency for the last century.

Recoinage of Gold in 1774.

In the year 1774 and subsequent years, we had a general recoinage of our gold currency, which forms the next prominent feature of our mint history. The avowed object of this recoinage was a reformation of the light and defective coins then in circulation; and the motive for doing so was to prevent the new and heavy coins from being selected from the circulation, and melted for the high price which the gold brought in the state of bullion. In fact, L. 4 of the gold coin then in circulation would not weigh more than an ounce; and, by reference to the prices paid by the bank for gold, we find that this was the market price. The holders of bank notes demanding new and heavy coins for them, required the bank to have a large coinage of gold annually, to supply this demand. These coins were melted, and sold in the state of bullion to the bank for the high price of L. 4 *per oz.* To remedy this inconvenience, the recoinage was completed. And it had the effect desired; for the price of gold, for upwards of twenty years, never exceeded, but was rather under its mint price.

Political economists have disagreed as to the cause of the high price of gold previous to the recoinage. Dr Smith says, "By issuing too great a quantity of paper, of which the excess was continually returning, in order to be exchanged for gold and silver, the Bank of England was for many years together obliged to coin gold to the extent of between eight hundred thousand and a million a year; or, at an average, about eight hundred and fifty thousand pounds. For this great coinage the bank, in consequence of the worn and degraded state into which the gold coin had fallen a few years ago, was obliged frequently to purchase bullion at the high price of L. 4 *per oz.*, which it soon after issued in coin at L. 3, 17s. 10½d. an oz.; losing in this manner between 2½ and 3 *per cent.* upon the coinage of so very large a sum. Though the bank, therefore, paid no seignorage, though the Government was properly at the expence of the coinage, this liberality of Government did not prevent altogether the expence of the bank."

Mr Ricardo very justly remarks upon this passage, that, "on the principle above stated, it ap-

pears most clear, that, by not reissuing the paper thus brought in, the value of the whole currency, of the degraded as well as the new gold coin, would have been raised; when all demands on the bank would have ceased;" or, in other words, the price of gold would have fallen to its mint price.

Coinage.

Mr Buchanan is not of this opinion; for he says, "that the great expence to which the bank was at this time exposed was occasioned, not, as Dr Smith seems to imagine, by any imprudent issue of paper, but by the debased state of the currency, and the consequent high price of bullion. The bank, it will be observed, having no other way of procuring guineas but by sending bullion to the mint to be coined, was always forced to issue new coined guineas in exchange for its returned notes; and when the currency was generally deficient in weight, and the price of bullion high in proportion, it became profitable to draw these heavy guineas from the bank in exchange for its paper; to convert them into bullion, and to sell them with a profit for bank paper, to be again returned to the bank for a new supply of guineas, which were again melted and sold. To this drain of specie the bank must always be exposed while the currency is deficient in weight, as both an easy and a certain profit then arises from the constant interchange of paper for specie. It may be remarked, however, that to whatever inconvenience and expence the bank was then exposed by the drain of its specie, it never was imagined necessary to rescind the obligation to pay money for notes."

Mr Ricardo remarks upon this passage, that "Mr Buchanan evidently thinks that the whole currency must necessarily be brought down to the level of the value of the debased pieces; but surely by a diminution of the quantity of the currency, the whole that remains can be elevated to the value of the best pieces." With this opinion of Mr Ricardo we cordially agree, and it is upon this principle that a seignorage can be laid upon coinage, without any one directly paying for it as a tax. By restricting the quantity of a currency, this seignorage may be 10, 20, or even 50 *per cent.*, and the price of gold neither raised above its mint price, nor the bank subjected to a run for guineas.

During the period of these important transactions, New Constitution of the Mint remained without alteration. It had not, however, escaped the attention of the legislature, for we find that, on the 7th February 1798, his Majesty, by an order in Council, was pleased to appoint a Committee of his Privy-Council "to take into consideration the state of the coins of this kingdom, and the present establishment and constitution of his Majesty's mint." The first effort of this committee was to advise the erection of a new mint, with improved machinery, which desirable object was accomplished between the years 1805 and 1810: And in March 1815, a new constitution was introduced, founded upon a very valuable *Report*, drawn up and presented to this Committee by the Right Honourable W. Wellesley Pole, who had been appointed Master of the Mint in the preceding year.

We cannot better explain the whole constitution

Coinage and bearings of the establishment, than by detailing the rules, regulations, and instructions, applicable to the duties of the different departments.

The proper duties of the Deputy-Master and Worker are,

To receive, on account of the master and worker, his Majesty's own bullion of gold and silver, as well as the bullion of any other person, brought to the mint for coinage :

To give acknowledgments for the same, specifying the number of ingots, or parcels of coin, according to the purport of any invoice or bill delivered therewith :

To see the ingots safely deposited in the care and joint custody of himself and the master's assayer, for the purpose of being assayed previous to their importation into the office of receipt :

To cause the ingots, when duly assayed, to be brought into the office of receipt without delay, there to be weighed in the presence of the importers and cheque officers :

To make out a mint bill, to be delivered to the importer, testifying the weight, fineness, and value of the several ingots, &c. together with the day and order of the delivery into the mint, and to sign a receipt annexed to the said bill, witnessed by the Comptroller and King's clerk :

To give directions to the master's first clerk, for the combining or pottng the ingots for the melting, with the proper portion of alloy ; and to see that the same be duly entered by the said first clerk and melter, in the pot book, and the said book examined by the Comptroller and King's clerk ; and to deliver out of the strong-hold such ingots and bullion as are potted, and charge the melter therewith, according to the standard weight of each pot :

To keep an account of the bars received from the melting-house, and delivered to the moneyers, and also of the scissell returned by the moneyers to the melter, for which their respective receipts will be given and entered in the pot-book, that they may be charged therewith :

To receive the coined monies from the moneyers, after the same have been duly tried at the pix by the King's assayer, Comptroller and King's clerk : and to deliver the same to the importer, receiving back at the same time the mint bill which had been given ; or if the same be not cleared off, to require that such portion thereof as has been delivered, be indorsed on the bill by the parties, by a receipt, till the whole be discharged :

To seal and lock up in the usual chest, in conjunction with the King's assayer and comptroller, the pieces reserved for the public trial of the pix, and to make good to the parties the pieces so taken, by payment in their sterling value ; charging the same to the public expence :

As first executive officer of the mint, to watch over every branch of the department, and to inspect and oversee, as much as lies in his power, the meltings, assayings, and all the different processes of the coinage, and to report to the master on the conduct of the officers :

To draw and indite all letters, instructions, com-

missions, and other writings agreed upon and ordered by the master and worker, for the service of the office, and to have the same recorded by the clerk of the papers :

To receive all monies issued at the exchequer or elsewhere, for the service of the mint ; and to keep the public account of the master, to be laid annually before the auditors of public accounts, with the proper vouchers, the said account to be signed and attested by the master himself :

To make quarter books of the salaries, wages, allowances, &c. due to the several officers, clerks, artificers, and others belonging to the establishment ; and to make payment thereof on the quarter days, namely the 5th of January, the 5th of April, the 5th of July, and 10th of October, whenever there shall be funds for that purpose : Also, to pay the moneyers and melters charges for coinage, according to the rates set forth in their respective agreements with the master ; the same to be payable out of the monies issued for the service of the mint, the salaries, &c. being previously discharged : Also, to pay the incidental expences and disbursements usually incurred in the different offices ; and to pay the solicitor his account for disbursements in carrying on prosecutions for offences against the laws relating to the coin, out of such monies as shall be impressed from time to time, for that service, exclusive of the ordinary allowance :

To receive all the fees arising to the master's office under the indenture or otherwise, and to apply the said fees to the payment of the master's salary, in the manner directed by the act 39th Geo. III. and to account for the same to the Lords Commissioners of his Majesty's Treasury, by half-yearly statements, showing the deficiency of the fees, and the sum to be provided, or the excess, as may happen ; and to make out a yearly account to the Treasury :

For this office he is to give the usual security, or such other as may be required by the Lords of the Treasury :

In conjunction with the comptroller, to inspect and examine the accounts of the clerk of the irons, as to the dies supplied to the engraver and moneyers, and the faulty ones destroyed :

To attend the duties prescribed by the act 14th Geo. III. respecting the standard money weights.

The proper duties of the King's Assayer are,

To keep a book of the assays made by him, of all such gold and silver as may be brought into the mint, whereby the quantity and fineness may appear :

If the master of the mint, or the merchant, or importer, who brings his gold or silver for coinage, may not accord between them of the true value of the bullion, or if it be not malleable and fit for working, or sufficiently nigh to the standard, according to the customs of the mint, the King's assayer is to try the truth in that part, in the presence of the master and comptroller, and the master shall receive the same in manner as it becometh :

To report (after the bullion has been weighed, potted, and melted) the assay of every several pot, commonly called the pot assay, which pot assay

Coinage.

Coinage. shall be made of some bar of the said bullion, to be taken by the comptroller, the King's assayer, or surveyor of meltings, or any one of them, after the pot is cast out; the said report to be made in writing, and delivered through the office to the surveyor of meltings: **Coinage.**

To take care that the bars of gold and silver be melted, and the monies made agreeably in fineness, to the indented trial plates, made by direction, and ordered to be used by the royal authority; whereof one trial plate for the gold, and one for the silver, shall remain with the King's assayer:

In conjunction with the other principal officers to oversee and survey the assaying, and melting, and making the monies, at all times and in all places; and endeavour and procure that the said monies, and every of them, shall be properly made and perfected:

To see and procure, with the comptroller, and weigher, and teller, that the balances and weights be put to point from time to time, when they shall need it; so that no default be found in them, to the hurt of his Majesty and his people:

To make proof (by a process called the pixing) of the monies before their deliverance to the bringers in of the bullion; the said proof to be made in the presence of the master and worker, comptroller, and King's clerk, by an assay to be taken of the fineness as well as of the weight, by such quantity, and after such sort as shall be agreed on, or as has been customary, namely, by weighing the pound weight in tale; and taking one piece out of every journey weight of gold and silver respectively for the assay of the fineness, as directed by the mint regulations. To report thereon, and the report to be entered in the pix books:

In conjunction with the master, and worker, and comptroller, to see a portion, namely, one piece out of every journey weight of the said monies (after they have been proved to be good), ensealed in a packet, and put into a box (called the pix-box), to be locked up under the separate keys of the said officers, there to remain until trial thereof by jury (called the trial of the pix) shall be made before the King, or such of his council as are usually appointed at Westminster, or elsewhere, for that purpose:

He shall be bound to instruct in the art of assaying, the probationer assayer, who shall be nominated by the King's assayer, and approved by the master and worker:

To attend the duties prescribed by act 14th Geo. III. respecting the standard money weights.

The proper duties of the Comptroller are,

To enter on record in a journal or ledger, all such bullion of gold and silver as shall, from time to time, be brought into the mint, which entry shall comprehend the weight as declared by the weigher and teller; the fineness as reported by the master's assayer; and the value of the said bullion, the parties names that brought it, and what day:

To deposit at the office of receipt in the strong-hold, of which he shall possess a key (in conjunction with the deputy-master and worker, and King's clerk), the bullion, after it shall have been receiv-

ed, and the assays and weight thereof made, reported, and entered, there to remain until it is required to be delivered by the deputy-master for the meltings:

In conjunction with the King's clerk, to take an account of the ingots delivered by the deputy-master out of the strong-hold for the meltings, according to the entry made by the master's first clerk and melter in the pot-book, and to examine the said book as to the calculations of the quantities and fineness, of all manner of gold and silver and alloy, combined and put to each pot respectively for the meltings, and to subscribe the same with his initials:

To take also an account and oversee the weighings of the bars and scissell, passed through the office between the melter and moneyers; for which their respective receipts shall be entered in the pot-book:

To keep an account of all the deliveries of the monies, and to ascertain, at the end of every month or oftener, the balances due by the master to the several importers, and also the balances in the hands of the moneyers and melter, and agree the same with the deputy-master, who is to charge the said moneyers and melter therewith accordingly:

In conjunction with the other principal officers, to oversee the melting, rolling, sizing, and making, the monies, at all times and in all places; and endeavour and procure that the said monies and every of them shall be properly made and perfected:

To see and procure, with the King's assayer, and weigher, and teller, that the balances and weights shall be put to point from time to time when they shall need it, so that no default be found to the hurt of his Majesty or his people:

To attend the proof and trial (called pixing) of the monies before their deliverance to the importer, and to try the weight of some of the pieces in each journey weight singly, as a check that there may be no great variation from the true weight; and also to retain two pieces from each journey weight, one to be delivered to the King's assayer for his assay, and the other to be locked in the pix-box, to be tried before the King or his council.—to document the parcel containing the pieces for the pix, and with the other officers enseat the same, and lock it in the pix-box:

To deliver upon oath, before one of the Barons of Exchequer, a roll, which shall be called a Comptroller's Roll, containing an account of all the gold and silver monies coined monthly in the said mint:

In conjunction with the deputy-master to inspect and examine the accounts of the clerk of the irons, as to the dies supplied to the engraver and moneyers, and that the faulty ones be destroyed:

To attend the duties prescribed by act 14th Geo. III. respecting the standard money-weights.

The proper duties of the Superintendent of Machinery and Clerk of the Irons are,

To inspect, from time to time, the several steam-engines and boilers, and the machinery, apparatus, and implements, used in the coinage, and to see that the same are kept in proper order for immediate working, at all times:

To oversee and direct, in conjunction with the

Coinage. company of moneyers, the artificers and workmen employed by Government about the machinery, in doing all manner of work that may be expedient; and likewise in the construction of all the smaller implements and tools necessary to carry on the coinage, upon the principle of the machinery erected; the repairs and work being ordered under the authority of the master and board of mint officers:

To superintend the working of the machinery, and instruct (to the best of his ability) the officers and moneyers in the use and management of it; and to report to the board upon any neglect or misuse:

To examine the several accounts of expences incurred in the machinery,—certifying, in pursuance of the agreements entered into between the master and the moneyers, the charges, both in respect to the bills, and also the wages to the artificers, which shall respectively be borne both by the Government and the moneyers.

As Clerk of the Irons,

To superintend the die press-rooms, and purchase, or procure to be forged, at the cheapest rate, to be approved by the board, all such dies as shall be ordered by the board, and to take care that the same are of the best quality, and properly forged:

To oversee the workmen in the die press-room, and that the dies be skilfully sunk and hardened, and properly turned; and to attend to all matters and things for the well ordering and conducting this service:

To keep a true account of all the blank dies, matrices, and puncheons, for coinage, which shall be delivered to the engravers, or that shall be sunk or stamped by the engravers, and after stamping made fit for use and hardened:

To require the engravers, monthly, to return as many dies as shall be found faulty and worn:

To give an account, as often as required, to the master and comptroller, of the blank dies delivered to the engravers, and the faulty ones returned, that a just account may be kept, and all the faulty dies defaced:

To unlock, and be present, whenever the great die-press for multiplying the dies is used; to be responsible for its not being applied for improper purposes; and that no medals, pattern-pieces, or coin of any description be struck, but by a written order from the master or his deputy.

The proper duties of the King's Clerk, and Clerk of the Papers, are,

To attend the weighings in, and enter in his ledger-book an account of all such bullion of gold and silver, as shall be brought into the mint, describing the weight and fineness as reported, the parties names that brought it, and the day:

To deposit at the office of receipt in the strong-hold, of which he shall possess a key in conjunction with the deputy-master and comptroller, the bullion, after it shall have been weighed in, and the weight and assays reported; there to remain until it shall be required to be delivered over by the deputy-master for the meltings:

In conjunction with the comptroller, to take an account of the ingots delivered by the deputy-master to the melter, as set down in the pot-book, and to examine the calculations of the pot-book as to the quantities and fineness of all manner of gold, and silver, and alloy, put to each pot, and to subscribe the same with his initials:

Also to take an account and oversee the weighing of the bars and scissell passed through the office between the melter and moneyers, for which their respective receipts shall be entered in the pot-book:

To attend the pix and deliverance of the monies, and record the same, and agree the master's, melter's, and moneyer's balances, up to the end of every month:

To enter (as clerk of the papers) in the record-book, all office-letters, papers, appointments, warrants, and proceedings of the board:

To assist the deputy-master in the secretary department, and instruct the master's second clerk in the keeping the proper entries of bills and accounts for expences incurred, or in making copies of all such papers as shall be required by the master or his deputy, or by the board.

General Instructions for the common duties of the Principal Officers (before-mentioned), to be by them observed.

To make their ordinary habitations and abode in the houses assigned them within the mint:

To meet in the board-room at the mint office every Wednesday (after the delivery of the monies), or on such other day and hour as the master, or the service of the mint, shall require, there to form a board. Three members (the master or his deputy being one) are competent to act:

To consult together, and order all business appertaining to them concerning the office, determining the hours of attendance of the several officers, the receipts of the bullion, and the delivery of coin:

To consider and give directions to the solicitor of the mint, from information laid by him before the board, for undertaking prosecutions for offences relating to the coin, and require him to report, from time to time, as to the state of the prosecutions and convictions:

To take up and employ such smiths, workmen, and labourers as may be severally wanted in the die department and assay offices; and for assisting in the portorage and weighing of the bullion and coin in the office of receipt, and to order the superintendent of machinery and clerk of the irons, to purchase or procure to be forged, all such dies as are necessary for the coinage or service of the mint, and to provide all necessaries, and do all manner of business within the mint, as may be needful:

To observe, follow, and perform, all orders, warrants, or significations of the master and worker, whether grounded upon warrants from the King, the Lords of the Committee of Council for coin, or the Lords Commissioners of the Treasury; and in all things to obey jointly or severally, in their respective places, such directions as he shall from time to time judge necessary and fit to give for the service of the mint:

Coinage.

To see that the accounts of the office for the receipt of the bullion and delivery of the coin, as well as the check and control thereof, be kept in due manner, as prescribed, and that the comptrolment roll of the monies, coined monthly, be exhibited yearly to the auditors of public accounts :

To see also that the receipts and payments of all monies for the service of the mint, be charged and accounted for in the master's public account, and that all bills, accounts, and statements, belonging thereto, be examined and allowed under at least three signatures of the principal officers, of which the master's deputy is to be one, previously to its being laid before the audit office :

Also to examine and report to the Lords Commissioners of the Treasury on the fees derived to the master's office ; and the application thereof, pursuant to the act 39th Geo. III. as stated in the receiver's account ; in order that the same may be declared and passed :

To prescribe to the under officers and servants, their several charges and duties, and to see the due performance of them, and in case of negligence or unfaithful conduct, to report to the master ; or, as far as the board are authorized, remove them from their situations :

Not to suffer the works of the mint to be viewed without an order signed by the master ; or any stranger or foreigner, not having business at the mint, without knowledge of his quality, to have intercourse with the officers while performing their duties.

The proper duties of the Master's Assayer are,

To receive from the master and worker all manner of gold and silver ingots brought to the mint :

To deposit the same in the joint custody of the deputy-master and himself, in the strong-hold of the assay office, till the assays are made :

To cut one or more pieces from each ingot (as he may think proper), and assay the same :

To make written reports of the assay of each ingot, describing the fineness, date, and name or mark of the importer, and keep a record thereof. To make also such remarks on the quality of the bullion as may be needful for the master's information, and to deliver the list usually given by the importer, of the purchase assays :

To give instructions for the classing of certain of the ingots together, so that the bullion may be mixed and worked as close to the standard as possible, and advantages procured by the mint assay :

To deliver the ingot when assayed into the office of receipt :

The proper duties of the Master's First Clerk and Melter are,

To superintend and carry on the operations of the meltings and refinings, according to agreements (stating the prices and conditions) to be made from time to time between the master and melter :

To attend the weighings in at the office, and rate and standard the ingots in conjunction with the other officers ; and their several accounts agreeing, to enter the same in his journal ; so that no difference may

arise between the deputy-master and himself as to the value of the bullion to be delivered to melt :

Coinage.

To arrange under the direction of the deputy-master from the said journal, and from the list of ingots classed by the master's assayer, the combination of the bullion for melting, and to make the proper calculations of the quantities and fineness of all manner of gold and silver and alloy put to each respective pot, and to enter the same fairly in a book (called the pot-book), and subscribe his initials to each pot so made up :

To receive the bullion so prepared from the deputy-master, to be deposited and melted under the joint custody and inspection of himself and the surveyor of meltings :

To melt and cast the bars (according to agreement), and, after they have been assayed and reported standard by the King's assayer, to deliver them into the office of receipt ; there to be weighed by the weigher and teller, in presence of a cheque officer, and passed to the moneyers :

To receive the returns of scissell, light work, and ends (according to agreement), from the moneyers, to be weighed in like manner, the receipts between the moneyers and melter for the bar and scissell being entered in the pot-book :

To receive from the deputy-master all such gold and silver as may be necessary to refine ; to make up an account in the pot-book of each charge, showing the standard amount, to be signed with his initials, and examined by the comptroller and King's clerk, and to supply a quantity of fine ingots, equal in standard weight by computation to the amount delivered to refine, the same to be assayed by the master's assayer, and weighed into the office of receipt, and rated and standardised so as to combine and pot with the coarse ingots :

To agree the balances remaining in his hands with the deputy-master, at the end of each month.

To employ and instruct the master's second clerk in the art of melting bullion ; and *lastly*, to be ready to do his work at all times, when he shall be warned by the master and worker ; and to attend to his Majesty's service as need shall require, both morning and afternoon, and to work so many hours every day (Sunday excepted) at such tasks as shall be thought fit by the master, and appointed by the board.

The proper duties of the Provost and Company of Moneyers are,

To superintend and carry on jointly as a company the several processes for the manufacture of the coin, in the rolling, annealing, blanching, cutting out, sizing, and stamping, according to agreements (specifying the prices and conditions) to be made, from time to time, between the master and worker, and the provost and company :

To receive the standard bars of gold and silver for making the monies, from the melter at the office of receipt, there to be weighed by the weigher and teller, in the presence of a cheque officer, and to give receipts for the same, to be entered in the pot-book :

To coin such quantities of the different species of the monies as shall be directed by the master (ac

Coinage. cording to agreement), and to bring the said monies (in clean pieces) into the office of receipt, in journey weights; there to be tried at the pix and weighed:

To deliver the monies proportionally in weight, according to the bars received; and if any thing lack of the weight at the time of deliverance, to content and pay unto the master the balance at the time of the delivery:

To make out of the bars which shall be delivered to them clean and fit to be wrought, seven twelfth parts into money, so that there be but five parts in twelve scissell:

To return the scissell, light work, and ends to be remelted, proportionally (according to agreement); the same to be delivered into the office of receipt, to be weighed by the weigher and teller, in the presence of a check officer, and to take receipts from the melter, to be entered in the pot-book:

To agree with the deputy-master, the balance remaining in their hands at the end of each month, that they may be charged therewith; and from time to time (as the master shall require) make full payment and deliverance of all manner of monies, with all convenient speed, in order to discharge the said balances, or bring in sufficient supplies of gold and silver, bullion, or ingots, equal in value, according to the weight and assay to be made thereof at the time:

Not to take either singly by the provost, or jointly by the company, any apprentice to be instructed in the art or mystery of a moneyer, or any part thereof, without the licence and permission of the master first had and obtained under his hand in writing:

To oversee, in conjunction with the superintendent of machinery, who is to direct the same, the artificers employed by government about the machinery, in doing all manner of work that may be expedient, and in the construction of the smaller tools and implements for the coinage:

To be ready to do their work at all times without denial, when they shall be warned by the master:

Duly to attend his Majesty's service, in the present way of coining, as need shall require, both morning and afternoon; and to work at such tasks, and so many hours every day (Sunday only excepted), as shall be thought fit by the master, and appointed by the board, according to the labour of their respective tasks, and the length of days:

Neither the provost, nor any of the moneyers, their apprentices or servants, at any time, to vend, pay, or distribute any piece or pieces of the coined monies, until the same shall have been delivered by them, according to the course of the mint, into the office of receipt, and duly assayed and pixed.

The proper duties of the Chief Engraver are,

To make and frame such draughts and embossments, or receive such models for engraving, as the master shall direct:

To engrave from the said designs or models all such matrixes and dies as the master shall direct, and the service of the mint require:

To oversee from time to time the multiplication of the puncheons and dies, in the die press-room, and to receive the dies from the superintendent

and clerk of the irons, that they may be delivered to the surveyor of the money presses in a proper state for the use of the coinage:

To return monthly to the superintendent and clerk of the irons, as many dies as shall from time to time be found faulty, and worn by using or otherwise:

Not to work, or make, or grave any puncheons, matrixes, dies, or stamps, for the making or coining of any money, but only in such places in the mint as shall have been assigned thereunto:

To oversee the striking of the monies in the coining press-room, and to direct all such dies as are faulty to be taken out of the press, and fresh dies put in, that the monies may be properly struck.

The proper duties of the Weigher and Teller are,

To weigh at the office of receipt, under the master's direction, all manner of bullion brought to the mint to be coined, or for the service of the King:

To weigh the bullion, according to such weight or draught (near to a journey weight) as has been customary:

All importations to be weighed in the presence of the deputy-master, or master's clerk, comptroller, or King's clerk, and the importer, who is to state the weight of each ingot from his list, for the guidance of the weigher:

To declare the weight aloud from his scale, that the same may be taken down by the officers and importers:

In conjunction with the other officers, to see that the bullion is free from dirt, and in a fit state for weighing, and to do strict justice, as much as in him lies, between the parties:

To weigh the bars and scissell, passed between the moneyers and melters, and declare the weight of each draught; and also all supplies of fine ingots received from the melter; and the balance or supplies of ingots, &c. made from time to time by the moneyers and melter:

To weigh the coined monies from the moneyers to be delivered to the importers in even journey weights, or to declare the plus or minus on each draught, that the same may be recorded, and the moneyers made answerable for the deficiency of weight or balance at the time of deliverance:

To attend the pix, and tell out the number of pieces contained in a pound weight Troy of the respective species of monies to be delivered to the King's assayer for trial:

To undertake by himself, or by a proper workman in the mint (according to an agreement of prices and conditions), to clean and adjust the beams, &c. in the office of receipt, and to keep the same in order, so that they be always ready and perfect for working.

The proper duties of the Surveyor of Meltings are,

To survey the meltings of all gold and silver, and to take care that the ingots or bullion, according to the number and description in the pot-book, with their proper alloy only, to be weighed by himself, be put into the pot they are respectively set out for:

Coinage.

Coinage.

To see that nothing but scissell or such returns of ends as be clean and good, of gold and silver, respectively, be put into the pots of scissell :

During the time the pots are melting not to absent himself, or to be out of view of the pots so melting, until they have been poured off :

To take two or more assay pieces from some bar or portion of each pot cast from the top, middle, or bottom, of the pot, as agreed with the King's assayer :

To fold up each assay-piece in a paper, docketed with a description of the ingots and alloy, or scissell, &c. melted in each pot, the number of the pot and the date, and to deliver the same to the King's assayer :

To possess a key of the strong-holds in the melting house, and not to suffer any bars of gold or silver to be delivered out of his custody, until such time as they have been duly assayed and reported good, which reports will be made to him in written notices, transmitted through the office by the King's assayer :

To keep a book containing the weight of all gold and silver as shall be molten from time to time, with the alloys put into the same.

The proper duties of the Surveyor of the Money Presses are,

To inspect the coining presses, and to have a distinct and separate lock upon each of the presses :

To be present at the striking of the monies, and not to suffer the presses to be used for striking any pieces or coins but such as the master shall direct :

To have the custody of the dies received from the engraver and clerk of the irons, to give out the same for coinage, and return the faulty ones to the chief engraver, to be delivered to the clerk of the irons :

To polish the dies, or oversee the doing of the same, when the moneyers are coining :

To inspect the monies, that they be well made and free from brokages, and faulty or dirty pieces ; and to do, execute, and perform, all such other works and services in the said office as the master shall direct and appoint.

The duties of the Probationer Assayer are,

To receive instructions from the King's assayer for acquiring a knowledge and proficiency in the art of assaying :

To do all such services in carrying on the business of the assay-office, as the King's assayer shall require, and the master direct.

The duties of the Master's Second Clerk are,

To make out fair copies and entries of all such accounts and papers as might be required in the master's office, and to do all such services in the said office, as the master or deputy-master shall direct or appoint :

To receive instructions from the master's first clerk and melter in the art and undertaking of the meltings.

The duties of the Assistant Engraver are,

To assist the chief engraver in the engraving of the

reverses, lettering, or such other parts of the dies as the chief engraver shall appoint :

To receive instruction from the chief engraver in the art of engraving, and to render all such services in the department as the chief engraver shall require, and the master direct.

The duties of the Mint or Bullion-Porter are,

To attend the office daily, if required :

To be present at all importations and deliveries at the office :

To mark on the assay paper the weight of each ingot weighed at the scale :

To arrange, with the assistance of the master's porter, the ingots in the strong-hold, and put them together in pots, to be carried down to the melting-house :

To oversee the under porters in giving all proper assistance at all the weighings, and in the receipt into the mint of all bullion, and deliverance of monies or bullion :

To give the regular notices for the attendance of the officers, and other persons at the office, for business, and to do all such services as shall be directed by the master or board.

The proper duties of the Warden of the Mint are,

In conjunction with the master and comptroller, and with the assistance of the King's assayer, to make the weights of a guinea and of a shilling, according to the established standards, and also parts and multiples of the same, to be presented to council, and, if approved, to become standard weights, to be lodged in the mint :

To have the custody of the said weights at the mint, in conjunction with the master and comptroller :

To make also, in conjunction with the master and comptroller, and with the assistance of the King's assayer, copies or duplicates of the said weights, to be lodged with an officer called the stamper of money weights :

To summons once, or oftener, in every year, by warrant under the hands of himself, the master and comptroller ; the stamper of money weights to appear before them, and produce the said duplicates of the standard weights, to be examined and compared with the standard weights lodged at the mint office in their custody :

To pay the salary allowed to the stamper of money weights out of monies to be entrusted to him for that service by the master of the mint :

No person to be appointed to act as deputy to the warden, without the sanction of the Lords of the Treasury.

The proper duties of the Stamper of Money Weights are,

To attend the summons of the warden, master, and comptroller, and to have the duplicate weights in his possession compared with the standard weights at the office, at least once a-year :

To adjust the duplicate weights by the said standard weights, that all weights for weighing gold and silver money may be regulated by the said duplicates :

To stamp the weights made use of in weighing

Coinage.

Coinage. the money, receiving a fee of one penny on every twelve weights stamped or marked pursuant to act of Parliament:

No other weights but those stamped by the stamper of weights, to be accepted by law, for determining the weight of the coins; and persons counterfeiting the stamps, or altering weights so stamped, to be fined and imprisoned:

Not to interfere with the weights of the founders' company, if they have their weights sized and marked as above:

To receive the salary allowed to his office from the warden or his deputy.

The proper duties of the Solicitor of the Mint are,

To attend the board of mint officers every Wednesday, or such other day as may be appointed, to lay before them such information and depositions, in regard to persons offending against the laws relating to coin, and to receive the board's orders for acting thereupon:

To act in conformity to such order, in the prosecution of all such persons as shall clip, counterfeit, melt down, wash, file, or diminish the current coin of the kingdom, or alter any counterfeit coin, knowing the same to be counterfeit, or be guilty of any crime or offence concerning the said coin or money, or against the laws relating to them:

For the better carrying on of the prosecutions that may happen, at the same time, in different counties, to substitute and employ such other person as he shall see fit in his stead:

To make out quarterly accounts of the expences of the prosecutions, with the proper vouchers, to be examined by the board of mint officers, showing the disbursements made by him; and to make an abstract account at the end of every year, of monies received and expended, that the balance may be ascertained and the account discharged.

Usual Routine of Business at the Mint.

We shall now proceed to state the regular routine of the business of the mint, when the processes of the coinage are going forward, under the various check-officers whose duties we have enumerated.

Gold. The Bank of England are the usual importers of gold bullion. When they bring a parcel of gold for coinage, say, for example, 12 ingots; on their being brought to the mint, they are deposited with the master's assay-master, and under the key of the deputy-master of the mint, where they remain until the assay-master has made an assay of every ingot separately. When he is ready to deliver the assay reports of the said bullion to the master and worker or his deputy, the importers are required to attend in the mint office of receipt, where the said assay reports are read over by the weigher and teller. The same are recorded, according to their numbers, in the journals of the master, comptroller, and master's first clerk. To render this more intelligible to our readers, we shall insert the form of an importation of gold, by way of example, and make the same into pots, for the process of melting, which immediately follows its importation. The letter B is for better, and W for worse, than standard fineness, and the figures on the left hand are the excess of fineness

above standard, and those on the right hand, the excess of alloy beyond standard gold.

Coinage.

Saturday, 20th September 1817.

Importation from the Governor and Company of the Bank of England, of 12 Gold Ingots for Coinage.

Rating.	Assay Report.	Weight of Ingot.	Rating.

		Standard 180	

A mint bill is given to the importer for this bullion, testifying the weight, and fineness, and value of the several ingots, together with the day and order of the delivery into the mint. A receipt is annexed to the bill signed by the deputy-master, and witnessed by the comptroller and King's clerk. When the said bullion is delivered to the importers in the state of coin, the mint bill is received back at the same time by the deputy-master and worker.

The first clerk and melter is next required to pot the gold for melting, and the same is recorded in the pot-book as follows:

Saturday, 20th September 1817.

FIRST POT.

Nos.	Bank Eng. 20. Sep.

These pots are delivered to the melter, and placed

Coinage. to the debit of his account in the books of the deputy-master, comptroller, and King's clerk.

If the melter does not immediately melt the bullion when delivered to him, it is placed in his strong-hold, to which there are two keys, one of which is kept by himself, the other by the surveyor of the meltings.

When the bullion is to be melted, the surveyor of the meltings is in attendance, and examines that the ingots correspond with the numbers recorded in the pot-book, and, when satisfied that they are correct, the ingots belonging to each pot respectively are charged into the melting-pot, and it is his duty to attend until they are melted and cast into bars, without ever leaving the melting-house.

When the betterness and the worseness of the ingots do not balance each other (as we see it does in the examples above), but when there is an excess of betterness, which requires an addition of alloy, it is calculated after the standard of 22 carats of fine gold, and 2 carats of alloy, being the English standard of gold. The alloy is weighed by the surveyor of the meltings, and put into the melting-pots in his presence. And when there is an excess of worseness, which requires an addition of fine gold to produce the standard of the coin, the same is weighed by the surveyor of the meltings, and put into the melting-pots in his presence.

The gold is melted in pots made of black lead. Those chiefly used in the royal mint are of foreign manufacture; and are less liable to break in annealing than pots of English manufacture, from their having more black lead and less clay in their composition. Before the gold is charged into the pots, the pot is placed in a furnace of 14 inches square, and 20 inches deep from the grate. It is placed on a stand usually cut from the bottom of an old pot, and is about an inch or inch and half thick. This is covered with coke dust, which makes the pot part from it when withdrawn from the furnace, when the metal is melted. To give depth to the pot, a muffle is placed upon it, which is in fact an old pot cut in two, and the wide end fitted to the mouth of the pot. The muffle is covered with the other half of the old pot, so that it is one pot inverted over another. The object of this contrivance is to give an additional depth of 4 inches of fuel above the pot, by which a more equal degree of heat is given to the melted gold, which is an object of great importance, otherwise there might not be an uniform mixture of the alloy and fine gold, which is easily effected at a proper degree of temperature. By removing the top which covers the muffle, the process of the melting can be inspected as required. The furnace is lighted by putting a little ignited charcoal over the grate, and around the melting-pot. About 4 inches of coke is put over the charcoal, leaving the door of the furnace open, and the damper, which communicates with the flue of the furnace, shut. As soon as the coke is properly ignited, the furnace may be filled to the height of the muffle with coke; and leaving the door still open, and the damper shut, the fire will gradually burn through, and not endanger the pot, by being too suddenly heated. When the

Coinage. pot is heated to a bright red, the gold is charged, and generally the pot, weighing from 90 to 105 lbs. Troy, is melted in one hour. When the metal is thoroughly melted, it is well mixed or stirred, with a rod of black lead, which is heated to a bright red before putting it into the metal. The pot is then withdrawn from the furnace, by first drawing a bar of the grate (which is moveable) on each side of the pot, and forcing all the fuel into the ash pit; a pair of tongs is then made to encircle the pot, to which is attached a lever, by which the pot is lifted upon the top of the furnace. The pot is then carried, in another pair of tongs, and its contents poured into two moulds, which produce two bars of 10 inches long, 7 inches wide, and 1 inch thick. The pot is returned to the furnace, the bars that were withdrawn replaced, and the ignited fuel put round the pot, and charged with more gold. A pot, by proper treatment, may be used eight or ten times in the course of a day.

From each pot melted, two pieces or samples are cut, one from the first poured bar, the other from the second. These are put in papers, marked accordingly by the surveyor of the meltings, who delivers them wrapt up in a slip of paper, which contains the numbers of the ingots of which the pot was composed, their gross weight, with the quantity of alloy or fine gold, as it may happen, which was added in the melting. The bars of gold, after being weighed by the melter for his own satisfaction, are placed in the strong-hold, under the key of the surveyor of the meltings, until the King's assay-master has reported their standard quality. If they are found to be the proper standard, he sends a written order, authorizing them to be delivered to the moneyers, for the purpose of making coin.

When the bars are delivered to the moneyers for coinage, they are carried by the melter to the office of receipt and delivery; where they are weighed by the weigher and teller, in the presence of one of the check officers, one of the moneyers, and the melter.

The moneyer gives a receipt in the pot-book to the melter for the gold so delivered, and the same is placed to the credit of his account in the books of the deputy-master, comptroller, and King's clerk. The same process is gone through when the moneyers return the portions of the gold, commonly called scissell, which they cannot make into money, and for the weight of which the melter gives a receipt in the pot-book, which is placed to the credit of the moneyers, and debit of the melter's account.

When silver bullion is imported into the mint, it passes through the same preliminary stages that we have seen the gold pass. The weight of an ingot of silver is from 50 to 60 lbs. Troy; they are numbered, assayed, weighed before the importers, and potted for melting the same as in gold. The only difference is in the pots, weighing from 400 lbs. to 450 Troy lbs. each. The silver is reported in ozs. and dwts.; and the standard computed to that of 11 ozs. 2 dwts. of fine silver, and 18 dwts. alloy. The pots are melted under the inspection and superintendence of the surveyor of the meltings; in every respect the same as the gold, excepting that three

Coinage. samples are taken for the assay, one from the first, the middle and last poured bar of each pot.

The process of melting silver, now practised at the Royal Mint, is a recent invention, and a very great improvement. The usual mode was to melt it in black lead pots, and a considerable coinage of tokens for the bank of Ireland was performed with the melt-
ings done in this way. The importations being entirely Spanish dollars, and the tokens of that standard, the melter could easily melt them in quantities of 60 lbs. Troy, which was done. The inconvenience of this mode was severely felt, because ingots of silver of various qualities could not be imported for coinage, from the difficulty of not being able to blend several together in one pot, so as to produce the proper standard of our money. So sensible was government of this imperfection in the mint, that, in the year 1777, Mr Alchorne, then master's assay-master, was sent to visit the mints of Paris, Rouen, Lille, and Bruxelles, and to collect information as to the arts of coining practised in those mints, and particularly the art of melting silver in large quantities. Mr Alchorne's intimate knowledge of the English mint, together with his various and extensive knowledge as a practical chemist, well fitted him for the important undertaking; and his observations on the coin and coinage of France and Flanders is exceedingly creditable to his judgment and knowledge.

It is worthy of remark, that it is on record in the books of the mint, that, in the recoinage of King William III. the pots of silver weighed 400 lbs. Troy and upwards; but every trace as to how this quantity of silver was melted is completely lost; and it is only conjectured that it was done in pots made of wrought-iron. But not a vestige of a melting furnace, fitted for such a purpose, is to be found in the Tower, nor a single record of the method practised.

In the year 1758, some trials for melting silver in wrought-iron pots took place, by means of a blast-furnace, but they were found so laborious, inconvenient, and profitless, as to cause the process to be abandoned.

In 1787, when some silver was imported into the mint for coinage, new experiments were made by the late Mr Morrison, then deputy-master and worker, and who conducted the meltings. A blast-furnace was again tried and abandoned. He next attempted to melt the silver in large black lead pots, containing from 100 to 120 lbs. Troy; but the repeated breaking of the pots, although it was attempted to guard them by outside luting, proved a great interruption to the business, and serious loss to the melter. Trial indeed was made with cast-iron pots; but these were found subject to melt, and the iron got mixed with the silver. The work too was continually stopped by the King's assayer, in consequence of the metal not being of the proper standard, it being always refined by the process of melting, and lading it with ladles from the pot.

Independent of these considerations, very great difficulty arose at the office in arranging the potting, previous to the operation. The practice pursued at the mint (in order to reduce the metal to standard),

of combining and blending the various ingots of better and inferior qualities, adding what little portion of alloy or fine metal that might be necessary to obtain accuracy, rendered it impossible, where the ingots weighed from 60 to 80 lbs. Troy, to pot them of a weight not exceeding 100 lbs. Troy. It therefore became necessary, in the first place, to reduce the larger description of ingots to a smaller size by melting, and these were again weighed into the office of receipt. Hence a double operation took place, occasioning additional labour, waste, and expence to the melter, and requiring extraordinary trouble and attendance on the part of the office. It was very obvious that this mode of conducting the silver meltings was extremely defective, and was in consequence abandoned.

The next experiments made were with a reverberatory furnace, built after the model of those used in the Lille mint. But no better success attended these trials, and the process was, as in former cases, abandoned. The imperfection here arose from the great refinement of the silver in the melting, by the oxidation of the alloy, and which the usage of the British mint does not allow the melter to supply, as in the French mints. In the French mints, as soon as the silver is in fusion, a sample is taken out and assayed, and copper is added in the proportion to the refinement of the melted silver (which is kept in fusion while the assay is making); the whole is well stirred, and immediately laded out and cast into bars.

In the years 1795 and 1798, several farther trials were made by the late Mr Morrison, who was indefatigable in his endeavours to perfect his department, with a view to attain the object so much desired,—that of melting large quantities of silver at once, without producing so much waste and refinement in the metal. In these experiments he tried three furnaces, each of a different construction; and though he was much nearer his point, there was still an imperfection, arising from the mode of dipping out the metal from the pot with ladles, which chilled the metal, and rendered the process extremely laborious and tedious.

No new experiments were made until the year 1804. Mr Morrison, having died in 1803, was succeeded in his office by his son, the present deputy-master and worker of the mint. The extreme scarcity and defective state of the silver coin at this time, arising from the defective state of the melting department, urged Mr Morrison to renew the experiments of his father. In following these experiments, Mr Morrison had in view the construction of a furnace adapted for the use of cast-iron pots,—the use of pots of a size capable of melting from 400 to 500 lbs. Troy, at one charge,—the adaptation of such machinery as would supersede the clumsy and wasteful process of lading the silver from the pots when melted,—and, lastly, the introduction of the use of moulds made of cast-iron, in place of those then used in the mint, and which were made of sand.

In all these objects Mr Morrison, highly to his credit, perfectly succeeded; and the silver melting department of the new mint was construct-

Coinage.

Coinage.

ed according to the furnace first used in the experiments which led to such a satisfactory result. The whole has been in use since 1811, and the department is capable of melting, with ease, 10,000 lbs. Troy of silver daily; as was done for several months during the late recoinage. (1817.)

We shall now proceed to a description of the machinery and furnaces of the silver melting department, together with the mode of conducting the process.

The upper part of Plate LXI. is a perspective view of the machine, for pouring the melted silver into the ingot moulds.

Fig. 1. AA, are the furnaces in which the metal is melted. These are air-furnaces, built of fire-brick, in the usual manner of melting furnaces, but, to render them more durable, the brick-work is cased in cast-iron plates, which are put together with screws. BB are the covers to the furnace; they are held down to the top plate of the furnaces by a single screw-pin for each; and, on the opposite side of the cover, a handle *a* is fixed. By pushing this handle, the cover is moved sideways upon its centre-pin, so as to remove it from the furnace mouth. A roller is fitted to the cover, to run upon the top plate, and render the motion easy.

The interior figure of each furnace is circular, 30 inches deep, and 21 inches in diameter; the bottom is a grate of cast-iron bars (each bar being moveable) to admit the air. Upon the grate is placed a pedestal or stand of cast-iron, of a concave shape, covered an inch thick with coke or charcoal dust, and upon which the pot is placed in which the silver is melted. The pedestal is nearly two inches thick, and is fully two inches broader in its diameter than the pot, the object of which is to protect the hip of the pot from the very high heat which the current of air ascending through the grate, when the furnace is at work, creates, and which would otherwise melt the pot. This precaution is essentially necessary, from the pedestal raising the pot so considerably above the grate, and from its being entirely surrounded by the fire in the furnace. If the furnace, however, is properly managed, there is no risk of melting the pot. On the top or mouth of the pot is placed a muffle, which is a ring of cast-iron, six inches deep, made to fit neatly into the mouth of the pot; the use of this muffle is similar to that used in melting gold, to give a greater depth of fuel in the furnace than the mere length of the pot, and which gives a greater degree of perfection to the process. The muffle is also extremely convenient, by giving a depth to the pot, if we may so speak, which enables ingots of silver to be charged, which are longer than the depth of the interior of the pot. The top of the ring or muffle is covered with a plate of cast-iron, to prevent the fuel from falling into the pot, and secure the metal from the action of the atmospheric air when in fusion. Each furnace has a flue 9 inches wide and 6 inches deep. The flue is 4 inches from the top of the furnace, and proceeds in a horizontal direction, and extends to the flue C, which is 9 inches square, and is carried up in a sloping direction

to the stack or chimney, which is 45 feet high from the grate of the furnace. Coinage.

When the furnace doors, BB, are closed, the current of air which enters at the grate ascends through the body of the furnace, and causes the fuel, which is coke, and which surrounds the melting pot, to burn very intensely. The degree of heat wanted, however, is very nicely regulated by a damper, which is fixed in the flue of each furnace, and exactly fitting the square of the flue, so that any portion of draught can be given to the furnace that may be wanted. The damper is a plate of wrought iron, fixed in a frame, and is easily moved in and out, so as to increase or diminish the size of the flue. It is fixed in the brick work of the sloping flue C, about 18 inches above the top of the furnace. The furnace doors B have small holes in them to look into the furnace; these are closed by stoppers or plugs of cast-iron.

When the furnace is put to work, it is lighted by some ignited charcoal being put upon the grate, and around the pot (for the pot is always in its place before the fire is lighted); upon the charcoal about three inches deep of coke is put—the door B is shut, and the damper is pulled out about two inches. When the coke is ignited, a similar quantity is put on, and so continued until the furnace is filled with ignited coke. The object of this precaution is to prevent the cracking of the cast-iron pot by being too suddenly heated—and it is generally about two hours before the pot can be brought to a charging heat, to do it with perfect safety. Before the silver is charged the pot is heated a bright red; it is then examined to see if it has cracked in bringing up, as it is technically called. This is done by placing a cold iron tool of considerable thickness in the centre of the pot, which immediately renders any crack visible to the eye. When satisfied that the pot is sound the silver is charged into the pot. With the silver is put into the pot a small quantity of coarsely grained charcoal powder, which coats the inner surface of the pot, and prevents the silver from adhering to it. When the silver is brought to the fusing point, the quantity of charcoal is increased until it is nearly half an inch deep on the surface of the silver, and which keeps the silver as much as possible from the action of the common air, and prevents that destruction of the alloy which would otherwise cause a considerable refinement in the metal. When the silver is completely and properly melted, it is well stirred with an iron stirrer, so as to make the whole mass of one uniform standard quality. The pot is then taken out of the furnace by the crane and conveyed to the pouring machine, by which its contents are poured into the ingot moulds.

Fig. 3. is the crane; it is supported by a strong column of cast-iron X, which is firmly fixed in masonry beneath the floor. The gibet of the crane marked WY is cast in one piece; it has a collar at *c* which fits upon a pivot formed at the upper end of the column X. At the lower part of the gib is a collar which embraces the column near its base. On these two supports the gib turns freely round, so that its extremity W may be placed over either of the

Coinage. furnaces BB. The wheel work of the crane is supported in two frames *zz*, which are fixed to the gib by three bolts; it consists of a cog-wheel *c*, upon the end of the barrel, on which the chain winds, and a pinion *b*, which gives motion to the cog-wheel. The axis of the pinion has a winch or handle (*a*) at each end to turn it round. The chain *d*, from the barrel, is carried up over the pully at *c*, which is fitted in a part of the gib immediately over the pivot at the top of the column X. The chain then passes over the pully W at the end of the gib, and has the tongs VT suspended to it. These are adapted to take up the pot between the hooks or claws T, at the lower ends. The two limbs are united by a joint like shears, and the upper ends V, are connected with the great chain by a few links. The pot has a projecting rim round the edge, and the tongs take this rim to lift the pot out of the furnace. The pot being wound up to the required height, by turning the handle *a*; the gib of the crane is swung round to bring the pot over the pouring machine, and it is lowered down into it, for the convenience of swinging the crane round a worm, which is fixed upon the column X at O, and a worm or endless screw is mounted in the frame *z* to work in the teeth of the wheel. The screw being turned by a winch on the end of its spindle will cause the gib to move round on the column.

Fig. 2. represents that part of the pouring machine in which the pot is placed. M is an axis which is mounted in the frame of fig. 1. by the pivots at its ends. To this axis is fixed a cradle, which receives the pot. The cradle is jointed together so as to open and shut, and the screw *m* draws the parts together until they will fit. The pot L is an arched rack, forming a continuation of the principal bars of the cradle. When the cradle is in its place, as in fig. 1. the rack L is engaged by a pinion K, and can thereby be elevated so as to pour out the metal at a lip or spout which is made in the edge of the pot for that purpose. The axis of the pinion K is turned by means of a winch D with a train of wheels DE, FG, and HI. The man who turns this winch stands before the pot, so as to see what he is doing. The frame of the pouring machine is sufficiently evident from the figure. It is so made as to leave an open space beneath for the carriage containing the ingot moulds.

Fig. 4. is a separate view of a pair of ingot moulds. The two parts R and S put together, and form a complete mould, as shown in fig. 5. The upper edge or mouth is a little enlarged to facilitate the pouring of the metal. The moulds are made of cast-iron. The part R has the bottom and one side formed on it, and the other half S has one side formed on it. Before the moulds are used, they are heated in an iron closet, which has flues surrounding it, and they are then rubbed on the inside with linseed oil.

PQ, fig. 1. is the carriage into which a row of these moulds are placed, as shown at 4, and they are screwed up close by two screws *pp*, so as to hold them tight; the moulds rest upon a plate, which is suspended by screws *q*, at each end, and can by that means be raised or lowered to suit different heights of moulds. The carriage is supported on four wheels QQ, which run upon a railway. PP is a rack fixed

to the bottom plate of the carriage; in this rack a cog-wheel N, acts; the cog-wheel is turned by a pinion which has a handle O, fixed upon it; by turning the handle the carriage is moved along upon the rail-way; and any one of the moulds 4, can be brought under the spout of the pot 2: then, by turning the handle D, the pot can be inclined so as to pour the metal into the mould until it is full.

In the silver melting-house there are eight melting furnaces, two cranes, and two pouring machines. Each crane stands in the centre of four furnaces, freely commanding the centre of each, and conveys the pots to the pouring machine. The eight furnaces are worked three times daily, and each pot contains, upon an average, 420 lbs. Troy, making the total melting 10,080 lbs. There are four men to each four furnaces; each party pour their own pots, and the whole meltings are finished from the time of first charging in the morning, in little more than ten hours.

The whole of the silver meltings, as we before observed, are conducted under the superintendence of the surveyor of the meltings; and he allows no silver to be delivered to the company of moneyers by the melter, unless he has a written order from the King's assayer master, authorizing such delivery.

The meltings are performed by contract with the master of the mint and his first clerk, as melter. He is responsible to the master for all the bullion he receives, and delivers weight for weight, which renders his situation one of considerable risk and great responsibility. He also finds security for the due performance of the duties of his office.

The bars of silver, of the approved standard, are delivered over to the moneyers, in the same manner as we have detailed respecting gold. The moneyers also perform the various processes of the coinage under contract with the master of the mint, always delivering weight for weight. They also give security for the due performance of the duties of their office.

The first process to which the silver bars are subjected, is that of flating, rolling, or laminating, in the rolling mill. The bars, before they are put through the rollers, are heated to redness, which makes them much easier rolled. They are heated in a reverberatory furnace.

When the gold bars are subjected to the same process, they are rolled cold, and a bar of an inch thick can be reduced to the thickness of a half sovereign without ever being annealed, and could be reduced much thinner if necessary, and not show the least symptom of cracking.

Fig. 6. is an elevation of one pair of rollers, and the wheel work for giving motion to them. A is the upper and B the lower roller; CC are the standards of the cast-iron frame which supports them. Each of these standards has a opening in it to receive the bearing brasses for the pivots of the rollers. The upper roller is suspended in brasses which are regulated by the large screws FF, which admit of placing the rollers at a greater or less distance asunder. This is shown by the separate figure of one of the screws; *hh* are the brasses, and *k* the hole to receive the pivot of the roller. On the upper part of the screw a collar *f* is fitted, and from this two bolts *gg* de-

Coinage.

ascend, and are fastened to the brasses *AA*, with nuts beneath. By these the roller is suspended, and by turning the screw round, the brasses rise or fall. The brasses *AA* are fitted very accurately into the grooves or openings in the standards *CC*.

For the convenience of turning both screws round together, each has a cog-wheel *F* fixed on the upper end of it. These are turned by two worms *HH*, fixed on a common axis, which has a handle *G* in front. See the plan, fig. 8. By turning this handle the upper roller is either raised or lowered, as is required, but will always be parallel to the lower one. The two standards *CC*, are firmly bolted down to the ground sills *DD*, which are of cast-iron, and are bedded in the masonry *EE*. The standards are farther united by bolts *a*. At the upper part *S*, is a cross bar fixed between the standards, to support a small table or platform, on which the metal is placed when it is to be presented to the rollers.

The rollers are put in motion by a steam-engine. The crank of the engine has a cog-wheel upon it which turns a pinion. Upon the axis of this is a very heavy fly-wheel, which turns with great velocity. On the end of the same axis, is a pinion which turns a large wheel *M*, and this gives motion to a long shaft *NN*, which extends beneath the rollers, and is continued a sufficient distance in the same direction, to turn two pair of rollers, one of which only are represented in the drawing. At *L*, a wheel is fixed on this shaft, to turn the upper roller *A*, by means of a wheel *K*, which is supported in the standards *kk*, and its axis is connected with a short shaft *rr*, with the square on the end of the roller *A*. *rr* Are the sockets by which the shafts are joined, and they admit of a little yielding when the roller is raised.

The wheel *O*, is fixed on the shaft *N*, to turn the lower roller *B*, by means of the wheel *P*; but the wheels *P* and *O* do not touch, being of smaller diameters, and an intermediate wheel is applied on one side, so that its teeth engage with both the wheels *O* and *P*; by this means the two rollers *A* and *B* are made to turn round in opposite directions, and then their adjacent surfaces will move together. The wheel *P* is supported in standards *pp*, and its axis *R* is connected by a shaft *Q*, with the lower roller *B*.

Fig. 7. is a gauge so ascertain the thickness of the plates, which are reduced by the operation of the rollers; it consists of two steel rulers, fixed fast together at one end, and the other end is a certain distance asunder, forming an opening between them, which gradually diminishes to nothing. The sides of the rulers are divided. In using this gauge to determine the thickness of a piece of plate, the edge of the plate is applied to the opening between the rulers, and the divisions of the rulers show the distance it will go into the opening before it fits tight, and the thickness is ascertained by the number of the divisions.

Plate LXIII., figs. 3. and 4., represent the machine by which the plates of metal from the rolling-mill are cut into slips of a convenient width, for cutting out the circular pieces or blanks, which are to form the coin. This width is generally that of 2 crowns, crowns, shillings, &c.

Coinage.

LL is a strong iron frame, which is screwed down to the ground sills of the mill, so that the cog-wheel *D* will be immediately over the shaft which turns the rolling-mill, and can be turned by a cog-wheel upon that shaft. The cog-wheel *D* is fixed upon an horizontal axis *BB*, which is supported in the frame *LL*. *AA* is a similar axis placed at the top of the frame, and turned round by a cog-wheel *C*, which engages with the wheel *D*. On the extreme end of each axis *A* and *B*, a wheel or circular cutters *E* and *F* is fixed. The edges of these cutters lie in close contact laterally, and overlap each other a little. The edges of the cutters are made of steel hardened, and they are turned very truly circular, and the edges which overlap are made very true and square. Whilst they are turning round, if the edge of a plate of metal is presented to them, it will be cut or divided just in the same manner as a pair of shears. *H* is a narrow shelf, upon which the plate is supported when it is pushed forwards to be cut, and *G* is a guide fixed upon the shelf; the edge of the plate of metal is applied against this guide, whilst it is moved forwards to the cutters. The guide is moveable, and the distance which it stands back from the cutting edges, or line of contact of the two cutters, *EF*, determines the breadth of the slip of metal which will be cut off.

To give these slips of metal the exact thickness which is requisite before they are cut up into blocks, they are subjected to a more delicate rolling; or they are drawn between dies by a machine, invented by Mr Barton, the present comptroller of the mint.

Fig. 7. Plate LXIII. represents the finishing rollers, viewed at the end of the frame, in order to show the manner of adjusting them; for it is only in those parts that they differ from the great rollers: *a* is one of the pivots or centres of the upper roller; it is accurately fitted in a collar of brasses, which collar is held down in a cell at the top of the standard by a cap *d*, with two bolts and nuts. These are not intended for the adjustment of the rollers as in the former instance, but the lower roller is moved for this purpose. The pivot *b*, of the lower roller, is received in a brass bearing, which is moveable, in the opening in the standard frame. The brass rests upon a wedge, *e*, which is fitted in a cross mortice through the standard. By forcing the wedge farther in the brass of the lower roller, it will be moved nearer to the upper roller. The standard at the other end of the rollers is made in the same manner, and the wedges of both must be moved at the same time. To give them motion, a screw, *f*, is fitted into each wedge, and upon these screws are worm wheels, *g*, which are both moved by worms cut upon an horizontal axis, then extends across from one side of the frame to the other, and has a handle at the end to turn it round by, and move the screws and wedges both in equal quantity; *l* is the table on which the metal is laid to present it to the rollers.

Plate LXII. contains drawings of Mr Barton's new machine for drawing the slips of metal between dies, by which a greater degree of accuracy is obtained in the thickness of the metal; the operation is similar to wire drawing.

Figs. 1. 2. and 3. represents a small machine for

Coinage. thinning the ends of the slips of metal, so that they will enter into the dies, through which the whole of the slip is to be drawn. It is a small pair of rollers, which are shown on a large scale, in fig. 1.; A is the upper roller, and B the lower: this has three flat sides, as represented; C is the slip of metal put between the rollers; D is a stop adjustable in the line of the motion of the slip of metal C. Fig. 2. is an end view, and fig. 3. a side view of the frame or machine in which the rollers are mounted. AB are the rollers, which are made to turn round together by pinions *a b*. F is a large cog-wheel, which is fixed on the end of the axis of the lower roller. This cog-wheel is turned by a pinion G, which is fixed on an axis extended across the machine, and having a fly-wheel fixed on one end, and at the other a drum H, to receive an endless strap, by which the machine is put in motion; a crank is formed on the middle of this axis, and a rod *d*, is joined to the crank, to connect it with the moving blade K of a pair of shears, of which the other blade L is fixed to the frame. The distance of the rollers is regulated by a screw *ee*, at the top of each standard. These screws have pinions at the top of them, and are turned round by a pinion which is placed between them, and engages the teeth of both pinions, so as to give motion to the two screws at the same time, when the middle wheel is turned round by a cross handle which is fixed to the top of it. If the slips of metal which are to be put in this machine are not exactly square at the ends, they are cut off smooth and square by the shears, which keep constantly moving; the end of the slip is then presented between the rollers, not on that side which would draw them in between the rollers, as in common rolling, but on the opposite side; when one of the flat sides of the lower roller comes opposite to the upper roller, then the piece of metal can be pushed forwards between the two, until the end stops against the stop D, as in fig. 1.; then as the rollers turn round, and the flat side of the lower roller passed by, the cylindrical parts of the roller will take the metal between, and roll it thinner at the end which is between the stops and the point of contact of the rollers.

Fig. 5. is a perspective view of the drawing machine at work.

Fig. 7. and 8. a section to show how the slip of metal C is drawn between the dies by the tongs, fig. 7.

Fig. 4. is a section of the steel dies. They are two cylinders AB of steel, made very hard and extremely true; these are fitted into two sliders DD, and are held fast by clamp pieces EE screwed against them. The steel cylinders are very accurately fitted into their beds in the slides, so that the steel shall be firmly supported and prevented from bending or turning round, and presenting but a small portion of their circumference against the slip of metal. The sliders D are fitted into a box, fig. 8. and 9.; they fit flat on the bottom of the box, and two clamps FF are screwed against the sliders to confine them to the box. The lower slider is supported by two screws *ff*; and the upper slider is forced down by a large screw G; this has a cog-wheel fixed on the top of it, with a pinion and lever to turn the screws round very slowly, and

regulate the distance between the dies. H is a clamping nut, fitted upon the screw, to take off all possibility of shake; the sliders are also bound fast sideways by screws tapped through the sides of the box, the points of which press upon steel plates between them and the sliders. In order to render the contact between the points of the screws, supporting the under slider and the point of the adjusting screw, forcing the upper slider, still more complete, two extending screws are introduced at the ends of the steel dies between the sliders, by which a sufficient degree of contact, to overcome the spring of the materials, may be excited before the dies come into action on the slip of the metal.

The box of dies is fixed at one end of a long frame, as is shown in fig. 5. This frame supports two axis, AA, one at each end. Upon these axis wheels are fixed to receive endless chains, BB, which move along a sort of trough or railway, formed on the top of the frame. The chains are kept in motion by a cog-wheel C, which is fixed upon the axis most remote from the box of dies. This cog-wheel is turned by a pinion D, on the axis of which is a wheel E, and this wheel is turned by a pinion F, on the axis of the drum G, which is moved by an endless band proceeding from some of the wheels in the mill, and which is thrown in and out of gear at pleasure by a tightening roller. The slip of metal is drawn through the dies by the chain, with a pair of tongs, fig. 6. and 7. *ab* are the two jaws of the tongs which are united with each other by the joint pin *c*. This has a small roller or wheel fitted on each end to run upon the railway on the top of the frame; *dd* are a similar pair of wheels, the axle of which is connected with two links *ee*; this axle passes between the tails of the tongs, but is not fixed to them. The ends of the links have a double hook formed on them as shown at fig. 7. The tongs run upon their wheels immediately over the endless chain, so that when the end *f* of the links *ee* is pressed down, one of the hooks catches on a cross pin of the chain, as in fig. 7. The axle of the wheels *dd*, acting between the inclined parts of the tails of the tongs, tends to throw them asunder, and, at the same time, the jaws of the tongs bite with very great force; the links *ee* draw the tongs along with the chain BB. The links are carried a long way beyond the axle of the wheels, and have a sufficient weight *h* fastened to them, which will lift up the hooked end *f*, and disengage it from the chain, except when there is a considerable strain on the tongs.

To use this machine, a boy takes hold of the tongs by the handle *r*, when they are disengaged from the chain, and pushes the tongs forward towards the box of dies. The tongs run freely upon their wheels, and the jaws open when moved in that direction, because two small pins *ii* are fixed across between the links, and acting on the outsides of the tails of the tongs, close them together, and this at the same time opens the jaws. The tongs are pushed up close to the box of dies, and the jaws enter into a recess N, fig. 8. which is formed for that purpose. Another boy takes a slip of metal, which is previously made thin by the rollers, fig. 1., and introduces it between the dies, and also between the

Coinage.

Coinage.

jaws of the tongs, which are open. The boy who holds the tongs now takes the handle *s*, which is fixed on the back of the tongs, and holds it fast, while with the other hand he draws the handle *r*, at the end of the links, away from the tongs. This has the effect of closing the jaws of the tongs upon the slip of metal between them; at the same time he depresses the handle *r*, and the hook at the end of the links *es* will be caught by the first pin of the chain, which comes beneath them. This puts the tongs in motion, but the first action is to close the jaws and bite the piece of metal with great force, in consequence of the axletree of the wheels being placed between the inclined planes of the tongs. When the tongs have closed on the metal, with all their force, they move with the chain, and draw the slips of metal through the dies, which operating upon the thicker parts of the slip with greater effect than upon the thin, reduces the whole to an equable thickness. When the whole length is drawn through, the strain upon the tongs is instantly released; and the weight lifting up the hook at the other end of the links, they are ready to be advanced again to the dies, to draw another bar. The frame, fig. 5. contains two pair of dies, and the same wheel serves for both. At the mint are two machines like that shown in fig. 5. They are placed side by side, with a sufficient space for the boys to work between them.

These machines were made by Mr Maudslay, under the directions of the inventor.

The slips of metal produced from this machine are considerably more uniform in thickness than when finished at the adjusting rollers; consequently the individual pieces are made more nearly to the standard weight, which was the object in view by this invention. This has become a point of great importance in the practice of the mint, from the remedy on gold in weight being reduced from 40 to 12 Troy grain. When the pieces cut from slips of metal prepared by the drawing-machine are pounded and weighed, which is telling the number of pieces in a pound Troy, sovereigns or half-sovereigns, the variations from standard either way seldom exceed 3 grains Troy. It is reckoned good work from the adjusting rollers when the variations are under 6 Troy grains.

The plates of metal, prepared by the adjusting rollers or the drawing machine, are cut out into circular pieces nearly of the size of the intended coin. This is done by the cutting out press, fig. 1. Plate LXIII. CCCC is a cast-iron frame which is fixed on a stone basement. E is the screw which is fitted through the top of the frame and actuates a slider F. At the lower end of the slider a steel punch *a*, is fixed. Its diameter is exactly equal to that of the pieces which are to be cut out, *c* is the steel die, which has a hole in it of a proper size to fit the steel punch; *d* is a box with screws for adjusting the die, so that the hole in it will be exactly beneath the punch.

The slider F is fitted into a socket G, which guides it so that it will descend correctly into the hole in the die. *b* is a piece of iron which is fixed a small distance above the die *c*; it has a hole through to admit the punch. Its use is to hold down the piece of

metal when the punch rises, otherwise the piece would stick to the punch.

On the upper end of the screw a piece Q is fixed, and an arm projects from it with a weight P at the end; and it is this weight which gives the necessary momentum to punch out the piece. D is a spindle fixed upon the piece Q in the line of the screw; it is supported in a collar A, at the upper end, and above the collar a lever DGF is fixed; at one extremity of this lever a roller F is fixed, and this is acted upon by projecting teeth, which are fixed in the rim of a large horizontal wheel, which is turned round by the power of the mill. This action is explained by fig. 2. which is an horizontal plan of the upper part of the axis. SS is part of the rim of the large wheel, and T one of the projecting cogs, which, when the wheel turns in the direction of the arrow, will take the roller F, at the end of the lever FD, and turn the lever round in that direction, which will wind up the screw and raise the punch out of the die. Also, this action draws a rod H, which is connected with the lever by a joint; the other end of this rod is connected with a bended lever, from the other arm of which a rod descends and has a piston fixed to it. This piston is fitted into a close cylinder; hence, when the piston is drawn up, it makes a vacuum in the cylinder, and the pressure of the atmosphere on the piston causes a reaction, and the instant that the roller F escapes or slips off from the tooth T, the reaction of the piston draws the joint H back, and makes the screw turn round in that direction, which causes the punch to descend into the die, and it will pierce out a piece from a plate of silver or gold which is laid upon the die, which piece will be exactly the size of the punch, which, as before mentioned, is the same as the intended piece of money. When the machine requires to be stopped, a catch K, is suffered to rise up and hook the lever G, so that it cannot return by the action of the exhausted cylinder and pierce the plate. This catch is shown in fig. 8. At K it is moveable on a joint *l*, and is thrown upwards by a spring *k*. To this spring a cord O is fastened, and the lower end of the cord has a tradle fastened to it. The boy who applies the plates of metal to this machine places his foot upon the tradle, and draws down the spring and the catch K, and then the machine will make a cut every time that a cog T of the great wheel S passes by; but if the boy relieves the tradle, then the spring K lifts up the catch *k*, as in fig. 8., and when the end of the lever G comes over the catch, it will be caught thereby, and held fast from returning by the action of the exhausted cylinder. The joint *l* of the catch K is made at the top of a long lever /N, of which *m* is the centre pin, when the lever G is detained by the catch K; if the end N of the lever is drawn towards fig. 1. it draws the lever G still farther, so that the roller F will be raised quite clear of the tooth T of the great wheel, and prevents any unnecessary wear of the machinery when the process is stopped.

Twelve of the cutting-out presses, fig. 1. are arranged in a circle round the great wheel SS, which is turned by a steam-engine, and has a large fly-wheel fixed upon the same axis, just above

COINAGE.

Coining. the wheel B, to regulate the motion. The stone basement on which the presses are fixed is circular, and the bearing A are all fixed in a circular iron frame, which is erected upon the stone basement by an iron column placed between each press. The whole forms a very handsome colonnade, and is placed in the centre of a circular room, which is lighted by a sky-light in the dome. The air-cylinders are concealed within hollow pilasters, which ornament the walls of the room, and appear to support the dome. The rod H is jointed to a piece *h*, which is fitted to slide upon the lever FG, and is moved by the screw I, so as to be fixed at any required distance from the centre, and give a greater or lesser effect to the reaction of the exhausted cylinder. R, fig. 1. is a strong wooden spring, against which the balance weight P strikes to stop its motion, when it has made its required stroke to pierce the plate.

This cutting-out machine was invented by the celebrated Matthew Boulton of Soho, who had a patent for it in 1790, and prepared it at that time for working the coining or striking presses, but having invented a better method of working the latter, he confined this plan to the smaller presses for cutting out the blanks.

The blanks after being cut out by the last mentioned machine, are carried to the sizing-room, where each individual piece is adjusted to its standard weight. The light pieces are selected for remelting: and the heavy ones, if not considerably beyond weight, are reduced to their standard weight by rasping their surfaces with a coarse rasp or file. The superior accuracy of Mr Barton's beautiful machine has considerably abridged the labour of this inelegant and unmechanical process.

The pieces thus adjusted, are in a state of great hardness from compression by the rolling and drawing processes, and by which, in fact, their latent heat has been squeezed out. They attain their softness again by being heated to a cherry red heat in a reverberatory furnace; after which, they are boiled in very weak sulphuric acid, which makes them very clean, and of a very white colour. When dried, either in warm saw dust, or over a very slow fire, they are in a state for the two next processes, which are the milling, and the coining or stamping.

Operation of
Milling.

The operation of milling is to be performed round the edge, to prevent their being clipped or filed (which was a fraud commonly practised upon the ancient money made before the introduction of milling or lettering round the edge). The construction of the milling-machine will be easily understood from the inspection of fig. 5. and 6. Plate LXIII.; fig. 5. being an elevation, and fig. 6. a plan of the same. The parts which operate upon the piece of money, consist of two steel bars or rulers, *dd* and *ee*, the adjacent edges of which are cut or fluted. The bar *ee* is immovable, being fastened down by two clamps *hh* to a cast-iron plate DD, forming the base of the whole machine; the other bar *dd* is prevented from rising by the pieces *gg*, but has the liberty of moving backwards and forwards in the direction of its length, and is guided in such motion by laying half its thickness in a groove formed in the plate DD. A rack CC is

fixed to the moving ruler, which engages in the teeth of the wheel B, mounted on an axis lying across at right angles to the ruler, and supported at its ends by two standards rising up from the Plate DD. On one end of the axis, a handle is fixed for giving motion to the machine. Two blanks are put into the machine at the same time, as shown at fig. 6., and the ruler *ee* can be made to approach nearer or recede farther from the ruler *dd* by the two screws *ff*, to take in a different sized piece between them. The operation of the machine is very simple. Two blanks being placed between the edges of the rulers, the handle A is turned round half a turn, which moves the ruler *dd* endways, sufficient to mark the blank all round the edge. The two milled pieces are then taken out, and two other blanks are placed between the rulers; the handle A being turned half round in an opposite direction, carries the ruler *dd* back again to the position in which it first stood: thus two more blanks are milled, and so on. The machine is placed upon a strong wooden bench, to raise it to a convenient height for the man who turns the handle; the blanks are placed in the machine by a boy who is stationed on the opposite side to that where the handle is.

Plate LXIV. is the coining-press, which stamps the money. Fig. 1. is an elevation of the press; CC B *Operation of Stamping.*

is a strong cast-iron frame, which is firmly screwed down upon a stone basement by the screws *cc*; the upper part B is perforated perpendicularly to receive the screw DD. One of the steel dies which strike the coin, is fixed to the lower end of this screw by a box, 4, and the other die is fixed in a box, 6, which is fastened down upon the base of the press. The heavy balance weights RR, are fixed on the top of the screw, which, being turned round, presses the upper die down upon the blank piece of coin which is laid upon the lower die and gives the impression, a sufficient force being obtained from the momentum of the loaded arms RR. The motion is communicated to the screw by a piece A, which ascends to the ceiling of the coining-room, and is worked by a steam-engine, with machinery, in the apartment in the room over the coining room.

Eight presses, similar to No. 1., are placed in a row upon the stone basement, and very strong oak pillars are erected upon the basement, and reach to the ceiling. Each press is contained between four such pillars, and iron braces are fixed horizontally from one pillar to another on the opposite side. These braces support blocks of wood against which the ends RR of the arms strike, to stop them from moving farther than necessary, as, without such precaution, the hard steel dies would sometimes come in contact and be broken. The piece of blank coin is contained within a steel ring or collar, whilst it is stamped, and this preserves its circular figure. The ring is shown at a large size at W, in fig. 5. V is a three-pronged spring which always bears the spring upwards: the opening through the ring V is made to fit upon the neck of the lower die T, fig. 6. When the ring is dropped upon the neck of the die, the upper surface of the ring and of the die will be in one plane. The ring admits of being raised up up

Coinage. on the neck, and will then form a recess or cell, which is just adapted to receive a piece of money. The collar W is made to rise and fall upon the neck of the die by means of the levers GG, fig. 5; these are fitted upon centre pins or joints in a large ring gg, which is placed on the outside of the box, fig. 6., containing the lower die T, and is fixed fast upon it, as shown at 5 and 6, fig. 1., by clamping the screws gg. The levers GG are forked at the outer ends to admit studs at the lower ends of iron rods EE, which rise up through holes in the solid metal of the press, and are united to a collar G, fitted on the upper part of the screw D. When the screw of the press is turned back, and the upper die is raised up, the rods raise the outside ends of the short levers G, and the inside ends depress the ring; a blank piece of money is laid upon the die, and when the screw is turned to bring the upper die down upon it, ready to stamp the impression, the levers G are released, and the triple spring V lifts the collar up, so that it surrounds the piece of money; and in this state the blow is struck. Immediately after the press returns by its recoil, and then the levers G force the collar down upon the neck of the die, and leave the piece free. The lower die is fixed in a box, fig. 6., by four screws H, which admit of adjusting it with precision beneath the upper die. The box, fig. 6., is screwed down upon the base of the press by four screws. The upper die is shown at S, fig. 3., which explains how it is fastened to the screw; vv are four screws, by which the die is held in a box, fig. 3. The box is fitted into a ring or collar, as shown by the dotted lines, F: see also fig. 1. The arms of the collar F are attached to the rods EE, by two nuts at each end, and this makes the collar F and the box 3. always follow the screw, and keep a close contact with the end of the screw, which enters into a cell in the top of the box, fig. 3., but leaves the screw at liberty to turn round independently of the box.

Fig. 2. is a ring which is fastened by its screws, *rw* to the screw of the press; a claw V, descends from the ring, and enters into cavity *o*, in the edge of the box, fig. 3., which cavity is near three times as wide as the claw V, and therefore allows the screw to turn round for a certain distance without turning the box, fig. 3., but beyond the limits of this motion the screw and die will turn round together. The intention of this is to press the upper die down upon the coin with a twisting or screwing motion; but if the die was to rise up with a similar motion, it would abrade and destroy the fine impression; for this reason the notch *o*, is so wide as to allow the screw to return, and raise the die from immediate contact with the coin, before it shall begin to turn round with the same motion as the screw.

Fig. 4. is a box which is screwed over the box for the upper die, as shown in fig. 1., in order to keep the upper die firm in its cell.

The great screw of the press is made cylindrical at the upper and lower ends, where it is seen at DD, fig. 1., and these ends are accurately fitted in collars, which are bound tight by the screws *aa*; the real screw or worm, part concealed within the solid metal B, and has no other office than to force the

die down, the guidance laterally being effected by the collars *aa*. **Coinage.**

It now remains to show how the press is made to remove every piece of money which it strikes, and to feed itself with a fresh blank piece.

Fig. 1. HIK, is a lever, of which I is the fulcrum; it is supported on a bar Q, fixed vertically from the cheek of the press, and steadied by a brace *h*. The upper end of the lever is actuated by a sector 7, see fig. 7., which is fixed upon the screw D. When the screw turns round, the groove in the sector being of a spiral curve, will move the end H of the lever to and from the screw; and the lower end K of the lever being longer, it moves a considerable distance to and from the centre of the press. *b* Is a socket or groove in a piece of metal, which is fixed to the perpendicular bar Q, and the upper end of the lever H is guided in this groove, to prevent any lateral deviation.

The lever K gives motion to a slider L, fig. 8., which is supported in a socket O, screwed against the inside cheek of the press, and the slider *l* is directed exactly to the centre of the press, and on the level of the upper surface of the die.

Figs. 8. 9. and 10. represent three views of the slider and socket; NMO is a kind of trough or socket in which the slider runs; this slider is formed of two pieces hollowed out on the sides, which are put together, and the two pieces are held together by screws. O is the part by which the socket is fastened to the press. The slider is a thin steel plate *p*, see also fig. 10.; it is made in two pieces, P and *p*, which are united by the joint *q*. The extreme end is made with a circular cavity; and, when the two limbs shut together as represented, they will grasp a piece of money between them, and hold it by the edge; but, if the limbs are separated, the piece will drop out. The limb *p* of the slider is opened or shut by the same movement which moves the slider endways in its socket. Thus a plate L is applied flat beneath the socket MN, and has an edge turning up and applying to the upright edge of the socket. A pin is fixed into this edge, and is embraced by the fork at the lower end of the lever *k*, fig. 1. By this means the sliding piece L is made to move on the outside of the socket N. It is kept in its place by a fillet *k*, fig. 9., which is screwed to the upright edge of L, and the fillet enters a groove formed along the upper surface of the socket N.

The sliding piece L is made to move the steel slider within the socket by means of three studs, which project upwards from the bottom plate of L, fig. 10., at *rrs*, and pass through grooves in the bottom plate of the slider, so as to act upon the steel slider P, in the manner shown fig. 10. The left hand piece *r* is received into an opening in the middle of the slider P, fig. 10. The other two studs *r* and *s* include the shank of the limb *p* between them, and these studs are cut inclined, so that, when the piece L is moved to the right, the studs *rs* will close the limb *p* until they are shut, and then the studs will carry the slider forward; but, if the sliding piece L is moved to the left, its studs will first close the limbs, and will then draw back the slider. On the top of the socket N a tube M is placed, and it is filled with blank pieces of coin; the

Coinage. tube is open at the bottom to the slider, and the pieces rest upon it. When the screw of the press is screwed down, the slider P draws back to its farthest extent, and the circle formed at the end between its limbs comes exactly beneath the tube M; the limbs being open, a blank piece of coin drops down into the circle of the slider, then the screw of the press, in returning, moves the lever HK and the piece L; this acts by its studs upon the movable limb p, and closes it upon the blank piece; the studs having now found a reaction, push the slider P forwards in its socket, and carry the piece forward upon the die, as shown in fig. 1., and which will push off the piece last struck. The screw having now arrived at its highest position, begins to descend, and the slider L to return; but the first action of the studs of the sliding piece L is to open the limb p, and then the slider withdraws, leaving the piece of money placed upon the die. As the screw of the press descends, the ring W, fig. 5., rises up to enclose the piece as before mentioned, whilst it receives the stroke, and the slider P at the same time returns to take another piece from the tube M in the same manner as before described.

Fig. 11. is a section to show the manner of mounting the lower die for a coining press. This is used in the French mint. V is a piece of metal or box, as it is placed upon the base of the press, and held down by a ring with screws t; this holds it fast, but admits of lateral adjustment. In the top of the box is a hemispherical cavity to receive the hemisphere W; the upper side is flat, and the die T is placed upon it, to hold the die down; it has a small projecting rim at the lower edge, and a rim X is screwed upon the outer edge of the box V, and binds the die down. The object of this plan is, that the die may always bear fairly to the money which is to strike.

Figs. 12. and 13. is a divided collar invented by Mr Droz, for striking money with the letters round the edge. X is a very strong piece of iron, which has a circular opening through the centre; into this, six segments w are fitted, and between them they leave an opening W, the size of the piece of money; the interior edges of these segments are engraved with the pattern or device which it is required to impress upon the edge of the piece. The segments are fitted in the piece X by centre pins y, fig. 12., upon one of which pins each segment can rise in the manner of a centre.

The intention of this is to have a piece of money placed on the die within the space W; then, when the pressure is made upon the piece, the die descends some space, and by this motion the segments close together around the edge piece, and imprint upon the edge of it. When all the segments come into one plane, the die arrives at a firm seat, and the metal receives the stroke which make the impression on its surfaces. The die is suspended in a sort of cup, which rises and falls with the screw, nearly the same as the collar F in fig. 1.

Disposal of the Coined Pieces. The coming room is under the superintendence of the surveyor of the money presses, whose duties we have already described. The money, when struck, is inspected under his directions, and passed through tubes of diameter, of the different species, which readily detects any pieces which may have been im-

Coinage. properly struck. The moneyers cannot coin, but in his presence, as he has every press under lock and key.

The money when examined is weighed up in journey weights for delivery to the importers of the bullion. The gold in 15 lbs.; the silver in 60 lbs. Troy.

Process of Pixing. Before this money, however, is delivered to the importers, it is carried to the mint office, to undergo inspection, and to be pixed. The inspector examines the coin as to its workmanship, and may reject it if faulty. The process of pixing is more important, as by it the perfection of the money, as to weight and fineness, is determined before it is delivered to the importers. The process of pixing, as it is called, consists in taking from every journey weight of gold and silver, a pound in tale promiscuously, by the weigher and teller. This is weighed in a very accurate balance by the King's assayer master, who declares aloud the minus or plus upon each lb., and which is recorded by the comptroller, King's clerk, and King's assay master. This determines whether the company of moneyers have made the money within the remedy allowed upon the pound Troy. As the remedy, however, upon the pound Troy is divided among the number of pieces in it, the same pound weighed is handed to the comptroller, who, in a delicate balance, weighs several pieces individually; and, if they exceeded the remedy, he could, in conjunction with the other check officers, order the coin to be remelted and recoinced at the expence of the moneyers. From the same pound weight of silver or gold, the comptroller takes two pieces; the one for the King's assayer master to assay, in order to prove that the company of moneyers have in no way or degree deteriorated the quality of silver or gold in any of their processes, or from the time of its having come into their possession. The other piece is sealed in a packet, and put into a box (called the pix-box), which is locked up under the separate keys of the said officers, there to remain until the final trial of the pix by jury, before the King, or such of his Council as are usually appointed at Westminster or elsewhere, for that purpose. When the King's assay master has proved the piece delivered to him to be of the right standard (and which, in this case, is taken as the average of the whole journey weight), he authorizes the money to be delivered to the importers of the bullion. During the period, however, in which the assay is making, the money is deposited in the strong-room of the mint treasury, under the separate keys of the master, comptroller, and company of moneyers. The money is delivered over to the importers by the weigher and teller, and in the presence of the master, comptroller, King's clerk, and one of the moneyers; the master receiving a receipt for the same, as described in the duties of the deputy-master and workers.

As the trial of the pix at Westminster is very ancient and curious, and though done in an open court, is yet so little-known, it may not be uninteresting to trace it from the earliest period in which it is to be found in our records,—to state the changes which it has undergone, and the manner in which it is conducted in the present times.

The Rev. R. Rudding, to whom we acknowledge

Coinage.

ourselves much indebted for much valuable information in the preceding pages, gives the following account of the trial of the pix.

"It does not appear that the ancients had any such public trial; and the earliest notice of the pix, which I have met with in any modern foreign mint, is in the reign of Philip VI. of France, in the fourteenth century; but whether the passage in which it occurs relates to a public trial, cannot be determined.

"The invention of it in this kingdom, or at least its introduction into our courts, is probably of high antiquity, for in the 9th or 10th of Edward I. it is mentioned as a mode well known, and of common usage. In one of those years the King, by his writ, commanded the Barons of the Exchequer to take with them Gregory de Roklesle (then master of the mint), and straightway, before they retired from the exchequer, to open the boxes of the assay of London and Canterbury, and to make the assay, *in such manner as the King's Council were wont to do*, and to take an account thereof, so that they might be able to certify the King touching the same, whenever he should please.

"From this record, which is the most ancient hitherto discovered relating to this trial, it appears that, previous to the above date, it had usually been made before the King's Council, but that, by the authority of the writ above quoted, it was then to be held in the Court of Exchequer, in the presence of the Barons. It was afterwards taken from their cognizance, and came again under the power of the Lords of the Council in the Star Chamber, where it is found to have been in the year 1595 (as appears from a verdict of that date), and where it continued until 1699, when it again became subject to the Court of Exchequer; under which it has remained to the present time.

"From memoranda of assays, which are still preserved in that court, it seems that this trial used to be annually; and the same is stated to have been the regular practice until the usurpation, when it was held at such times as the state pleased. At present, I believe it is not customary for the master to require it to be held until, upon his removal from the office, it becomes necessary, in order that he may receive his quietus.

"As the authority under which these trials are held occasionally varied, so did likewise the persons who sat as judges in the court. Thus, as we have seen above, they were first the members of the King's Council, then the Barons of the Exchequer, and again the members of the Privy Council, as judges of the Star Chamber, where sometimes the King himself presided; as did James I. at an assay, which was made upon the 9th May 1611.

"In 1643, a committee of Lords and Commons was appointed by order of Parliament, for the purpose of making this trial.

"At one period (in 1649), the court was held before the Lord President of the Council of State, the Commissioners of the Great Seal, and others of the Council of State, and Committee of Revenue, by virtue of an act of Parliament: at another (in 1657) by the Lords Commissioners of the Great Seal, assisted by the Lords Commissioners of the Treasury, the Justices of the several Benches, and Barons of the Exchequer, or some of them, under the authority of a warrant signed by the Protector Cromwell; and it is now com-

Coinage.

posed of such members of the Privy Council, as are expressly summoned for that purpose; the Lord High Chancellor, or, in his absence, the Chancellor of the Exchequer, presiding.

"The manner in which this trial was formerly conducted in the Court of Exchequer appears, from a verdict of the 11th year of Henry VI. to have been by an assay, made in the presence of the court, and of other persons who were appointed to assist, by the King's assay master, and to have been determined without the intervention of a jury.

"The earliest notice which has occurred, in which the judgment of professional artists was required to sanction, as a jury, the judgment of the court, is dated in the 37th of Elizabeth; when a trial was held in the Star Chamber.

"The number of the jurors has occasionally varied considerably. No less than nineteen names appear to the verdict of the 37th of Elizabeth; and in 1651 the moneyers speak of a jury of twenty-four men, whilst the number usual at the present time is no more than twelve.

"As I have not been able to discover any ancient ceremonial, by which the forms of this trial were regulated; I must now proceed to state the modern practice of summoning the court, and conducting the business of it.

"Upon a memorial, being presented by the Master of the Mint, praying for a trial of the pix, the Chancellor of the Exchequer moves his Majesty, in Council, to that purpose. A summons is then issued to certain members of the Privy Council, to meet at the house, which is now allotted to the office of Receiver of the Fees in his Majesty's Exchequer, at eleven o'clock in the forenoon, on a certain day. A precept is likewise directed, by the Lord High Chancellor, to the Wardens of the Goldsmiths' Company, requiring them to nominate, and set down, the names of a competent number of sufficient and able freemen of their company, skilful to judge of, and to present the defaults of the coins, if any should be found, to be of the jury, to attend at the same time and place. This number is usually twenty-five, of which the assay master of the company is always one.

"When the court is formed, the clerk of the Goldsmiths' Company returns the precept, together with the list of names; the jury is called over, and twelve persons are sworn. The president then gives his charge, which was formerly to be general, like the oath, to examine by fire, by water, by touch, or by weight, or by all, or by some of them, in the most just manner, whether the monies were made according to the indenture, and standard trial pieces, and within the remedies. But, in 1754, the Lord High Chancellor Talbot directed the jury to express precisely how much the money was within the remedies, and the practice which he thus enjoined is still continued. The other parts of the charge necessarily vary, according to the ability of the president, and his knowledge of the subject.

"When it is concluded, the pix is delivered to the jury, and the court is commonly adjourned to the house of the president, where the verdict is afterwards delivered.

"The jury then retire to the court-room of the duchy

COINAGE.

Cold.

of Lancaster, whither the pix is removed, together with the weights of the exchequer and mint, and where the scales which are used upon this occasion are suspended, the beam of which is so delicate, that it will turn with six grains, when loaded with the whole of those weights, to the amount of 48 lb. 8 oz. in each scale.

"The jury being seated, the indenture, or the warrant under which the master has acted, is read. Then the pix is opened, and the money which had been taken out of each delivery, and enclosed in a paper parcel, under the seals of the warden, master, and comptroller of the mint, is given into the hands of the foreman, who reads aloud the indorsement, and compares it with the account which lies before him. He then delivers the parcel to one of the jury, who opens it, and examines whether the contents agree with the indorsement.

"When all the parcels have been opened, and found to be right, the monies contained in them are mixed together in wooden bowls, and afterwards weighed.

"Out of the said monies so mingled, the jury take a certain number of each species of coin, to the amount of one pound weight, for the assay by fire; and the indented trial pieces of gold and silver, of the dates specified in the indenture, being produced by the proper officer, a sufficient quantity is cut from either of them, for the purpose of comparing with it the pound weight of gold or silver which is to be tried (after it has been previously melted and prepared) by the usual methods of assay.

"When that operation is finished, the jury return their verdict, wherein they state the manner in which the coins they have examined have been found to vary from the weight and fineness required by the indenture, and whether, and how much, the variations exceed, or fall short of, the remedies which are allowed; and, according to the terms of the verdict, the master's quietus is either granted or withheld."—*Archæologia*, Vol. XVI.

Method of
Making the
Dies.

We shall conclude our observations upon the subject of coinage, by detailing the mode of manufacturing the dies. An original die is engraven upon a piece of soft cast steel, of the size of the money to be made. The table of the die must be perfectly level or square. The impression engraved is, of course, cut into the steel, and its depth in proportion to the relief ultimately wanted upon the coin. When the engrav-

Coinage
||
Cold.

ing is finished, the die, or matrix, as it is called, is hardened. This is a very nice process, and requires considerable care to perform it. The die is put into a cast iron pot, completely embedded in animal charcoal, chiefly made from leather. The pot is placed in an air furnace in which coke is burned, which gives a more steady and uniform degree of heat. The square of the furnace is also considerably larger than the pot, that the die may have the greatest possible equality of temperature. When the die has attained its proper degree of heat, it is withdrawn from the furnace, and immersed in a large cistern of water, the temperature of which is kept as uniform as possible by a stream of cold water constantly flowing in and out of the cistern, while the process of hardening continues. It frequently happens, that in this process (either from the steel being faulty or heated to excess) the die will fly in pieces, and the whole labour of the artist is lost. When, however, the matrix is perfect, it is placed in the multiplying die press, which works in every respect like a coining press, but moved by men. An impression is taken from the matrix upon a blank die of cast steel, similar to the mode of impressing the money. The blank die is fixed as the lower die of the coining press; and, by working the screw of the press, which has very long and heavily loaded arms, the matrix is made to strike the blank die with great force, and bring its impression in relief upon its surface. The hardness, by compression of the steel, is so great, that an impression of the matrix cannot be obtained without annealing the die perhaps twice or three times, which is done in iron pots, as in the case of hardening, but are allowed to cool gradually. An impression taken in this way is called a puncheon die. When the engraver has given all the delicate outlines of the original to it, it is hardened in the same manner as its original, and used to give impressions to blank dies by a similar process, the impression being sunk into the dies, which dies being used for coinage, give the impression in relief to the money.

This important department of the mint is under the superintendence of the clerk of the irons, who never suffers the multiplying press to be used but in his presence. He has also the care of all the dies, and must account to the Board of Management for all matrices, puncheons, and dies, made and destroyed in the mint.

(A. A.)

COLD.

Cold is
Relatively

It is often disputed whether Cold has any actual existence, or should be considered as merely the privation of Heat. Nor is that question of a modern date; Plutarch attempted to discuss it, in his Tract *De primo frigido*, and the reasonings which he there employs, though abundantly vague, are yet curious. Cold, he says, affects the senses as well as heat; and it is not less active, since it condenses and consolidates bodies. He, therefore, inclines to the opinion, that cold is a distinct and independent power in nature. With the Stoic philosophers, he regards air as by its constitution cold and dark; and hence water drawn from a well freezes on being exposed to the atmosphere, while rivers over-

shadowed by high banks seldom freeze, and even where their surface congeals, the heat is not exhaled, but only driven down nearer the bottom.

It is contrary to sound physics to admit more principles than are indispensably required, and this argument alone may be sufficient for the rejection of cold as a distinct power in nature. What we term cold, in reference to our feelings, is merely the diminution of heat. But the existence and materiality of heat rest on a very different foundation. The introduction of heat into a body is accompanied by the infusion of a certain extrinsic repulsive force, and its passage through the mass is connected with a series of depending internal motions, which imply the regular expenditure of time and ve-

The Dimi-
nution of
Heat

Cold. locity. The contraction which follows on the diminution of heat, is due to the mutual attractive powers of the particles of the substratum, now exerted with less opposition. That expansion, again, which some fluids manifest in the act of congelation, proceeds from the operation of the principle of crystallization, with the recondite nature of which we are still unacquainted.

Concentration of Cold by Reflexion.

The notion that cold has a separate and independent existence appears, however, to receive some countenance, from the elegant experiment of collecting and concentrating the frigorific impressions in the focus of a metallic reflector. This curious fact is one of the oldest in physical science, but again lately revived, and combined with circumstances of peculiar interest. The experiment was first mentioned about the year 1590, by Baptista Porta, in the enlarged edition of his *Magia Naturalis*, when the four books of which it originally consisted were augmented to twenty, at the very time that his ingenious countryman, Sanctorio, had invented and applied to medical purposes the air-thermometer. Porta relates, that, if a shut eye be held in the focus of a speculum before which is placed a ball of snow, intense cold will be felt on the eye-lid.* Cavalieri, the celebrated discoverer of infinitesimals, in his work on the conic sections, printed in 1632, and entitled *Lo Specchio Ustorio*, extended the experiment to all impressions which he conceived to be propagated in straight lines—not only to those of heat and cold,—but to those of sound and even smell.† It was afterwards frequently repeated at Florence, by the Academy del Cimento, with the important addition of the thermometer, which that learned body had the merit of introducing into practice. Similar experiments were next performed by Mariotte in France.

Specula and burning glasses appear, in the sequel,

to have been allowed to fall into great neglect. We find scarcely any mention of their application to physical researches, till after the lapse of more than half a century, Kraft repeated, at St Petersburg, during the severe winter of 1740, the frigorific experiment of the Italian philosophers, with a reflector belonging to the Cabinet of the Imperial Academy. Ambitious to operate on a grand scale, he selected three huge blocks of clear ice, nearly of a cubical form, each side being 2, 4, and 5 feet; but to save the trouble of transporting them, he carried the speculum out of doors. No sensible effect, however, was then perceived by him, though he used the air thermometer on account of its extreme delicacy. In 1744, this Academician again resumed the observation, and with scarcely better success, having obtained only a doubtful cold of three degrees. The cause of the failure was evidently, his performing the experiment out of doors, and not in a warm room. The blocks of ice had, by long standing, acquired almost the same temperature as their ambient medium. Had the air happened to become suddenly colder, they might, from their relative condition, have excited impressions even of heat, and thus have perplexed philosophy for many years afterwards.

Such unsatisfactory results, from the action of a mass of ice of above a ton weight, seem, for a long time, to have shaken the belief in former experiments; and the subject was almost forgotten, when Pictet of Geneva, in 1781, repeated the original observation on a small scale, indeed, but with entire success. Since that time, a pair of brass reflectors, with a wire case for holding charcoal or snow, has been deemed an essential apparatus in every physical cabinet. The concentration of cold in the focus of a speculum, always excites surprise; and the experiment is often exhibited with a sort of mysterious air, as if

Cold.
Unsatisfactory Result.

Resumed by Pictet.

* Si quis candelam in loco, ubi spectabilis res locari debet, apposuerit, accedet candela per aërem usque ad oculos, ut illos calore, et lumine effendet; hoc autem mirabilius erit, ut calor, ita frigus reflectitur, si eo loco nix obijciatur, si oculum retigerit, quia sensibilis, etiam frigus percipiet.

† Cavalieri mentions that, with a spherical speculum made of lead and indifferently polished, he was able to inflame dry substances by the reflexion of a charcoal fire; and that, with a deep truncated parabolic speculum badly polished, he produced the same effect in the open focus, from a small fire of wood at the distance of five feet.—*Esperienza di questo hò fatto io, che con vno Specchio sferico di piombo ancor mal polito, hò acceso il fuoco nella materia arida al fuoco di carboni; e di più l'hò fatto con la superficie parabolica, cioè con vn canone parabolico, che hauea il suo foco vicino alla cima, essendo esso specchio parabolico trôcato pur nella cima, qual' era di stagno, e mal polito, tal che opponendolo al fuoco, ò alla fiamma di ben poca legna, nella distanza di tre braccia, ponendo la mano lì, dou'era la parte trôcato, et il foco della parabola, non vi si potea sostenere, anzi vi s'accese fuoco; la qual cosa potria alcuno applicare al riscaldameto delle stanze, ò alle distillationi, pp. 85. 86.*—In general, says this ingenious mathematician and philosopher, the same form of speculum which concentrates light and heat, must likewise collect cold, which spreads from its source, from a mass of snow, for instance, in straight lines. The hyperbola is, therefore, the figure which he thinks the best adapted for the purpose; and he proposes this for condensing the smells radiated from an odoriferous substance.—*Hora dunque basterà quello, che si è detto di sopra intorno al lume, e calore, potendo noi nell'istesso tempo intendere le medesime cose anco per il freddo, che dilatandosi dal corpo freddo ad ogni positione per linea retta, e perciò nell' infinite linee, che si partono dal corpo freddo, come dalla neue, essendoui dentro le parallele, che sone vnite dallo specchio parabolico, e le diuergenti, che sono vnite dall' ellittico, e le conuergenti vnite dall' iperbolico, con opporre alcun di questi specchi ad vna massa di neue, ò di ghiaccio, sentiremo nel loro foco essere il freddo fatto molto gagliardo, ma per questo effetto sarà più atto l'iperbolico di tutti, come quello, che raccoglierà maggior quantità di linee fredde; e questo basti ancora circa il freddo, potendosi forse in vn certo modo creder, che tale effetto accadesse anco intorno à gli odori, prouando noi dilatarsi pur quelli dalli corpi odoriferi verso ogni banda.* Id. p. 128.

Cold.

it established, or at least rendered possible, the distinct and material existence of cold. But, in fact, it is not more difficult to conceive the impressions of cold to be collected than those of heat. Both those impressions are only relative to the temperature of the atmosphere, which serves as the medium of their transmission. The one process terminates with the deposition of a portion of heat, the other with its abstraction.

Sources of Cold.

The diminution of heat, or the increase of cold, is produced in Nature under four different circumstances: 1. By the obliquity or absence of the sun; 2. By the tenuity of the higher atmosphere; 3. By the evaporation which takes place in dry air; and, 4. By the chilling impression shot downwards from a clear and serene sky.

Obliquity of the Sun.

1. In our temperate climates, the thermometer in winter very seldom descends 15 degrees on Fahrenheit's scale, below the point of congelation. But, in the higher latitudes, the intensity of the cold is often far greater. In the northern parts of Sweden and Russia, the rivers and ordinary lakes are frozen to the depth of several feet; wine, and even ardent spirits, become converted into a spongy mass of ice, and, as the cold still augments, it penetrates the living forests, and congeals the very sap of the trees, which occasionally burst from this internal expansion with tremendous noise. The Baltic Sea has been repeatedly covered with a solid floor of ice, capable of transporting whole armies, with all their stores and engines of war. Those waters, indeed, are only brackish; but the more northern ocean itself has often been frozen to a very considerable thickness. In Siberia and Hudson's Bay, and even in the northern provinces of Sweden, mercury has been at some times observed contracted by exposure into a solid semi-metal; and, consequently, the cold which then prevailed must have exceeded 71 degrees, or 39 below the commencement of Fahrenheit's scale.

Elevation of the Place.

2. In elevated tracts the increase of cold is very striking. Even at an altitude of three miles and a half, the air is generally 68 degrees colder than at the level of the sea. On the summit of the Andes, therefore, a thermometer would often sink perhaps under the beginning of Fahrenheit's scale; and it seems probable that mercury would naturally freeze in winter on the top of Mont Blanc. Mountains are hence regarded as the grand stores or depositaries of cold in the milder climates. In every country, therefore, the air of subterraneous caves, and the water of deep springs or wells, are during the summer months comparatively cold. Hence the obvious advantage of cellars, in addition to their preserving an uniform temperature, which is so favourable to the ripening of the liquors deposited in them. But the air at the bottom of an open and very deep pit must be colder than the mean state of the ground, for in all the changes which take place at the surface, the cold air will descend, and the warm air still float over the mouth of the pit. The wealthier classes of antiquity were accustomed, accordingly, to cool the wine for their tables, by suspending it for some time in a bucket let down near the surface of profound wells.

Cold.

Evaporation.

3. Evaporation is a natural process, by which heat is powerfully abstracted by the exhaling moisture, while this assumes a gaseous constitution in the act of combining with dry air. The fact seems to have been known in the warm regions of the east at a very early period of society, suggested probably by the familiar use of a rude unglazed pottery for all culinary purposes. The Egyptians, and other inhabitants of the sultry shores of the Levant, have, from the remotest ages, cooled the water for drinking in their porous jars. Athenæus reports, from a history of Protagorides, that King Antiochus had always a provision for his table prepared in that way. The water having been carefully decanted from its sediment into earthen pitchers (*υδρεια; κεραμεια;*), these were transported to the highest part of his palace, and exposed to the clear and keen atmosphere (*εναεραζουσαν*), two boys being appointed to watch them the whole night, and keep constantly wetting their sides. This labour of sprinkling the surface of the jars seems to have been afterwards spared, in consequence probably of the adoption of a more porous kind of earthen-ware. Galen, in his *Commentary on Hippocrates*, relates, that he witnessed the mode of cooling water, which was practised in his time, not only at Alexandria, but over all Egypt. The water, having been previously boiled, was poured at sun-set into shallow pans (*αγγυς οβαλινους*), which were then carried to the house-tops, and there exposed during the whole night to the wind; and to preserve the cold thus acquired, the pans were removed at day-break, and placed on the shaded ground, surrounded by leaves of trees, prunings of vines, lettuce, or other slow conducting substances.

The bottles or bags made of goat-skins, in which the wandering Arabs are wont to carry their scanty provision of water, allowing a small portion of the liquid to transude and exhale, render it by consequence comparatively cool, and better fitted to mitigate or allay the intolerable thirst created in traversing their sandy deserts. In Guinea, it is customary to fill gourds or calabashes with water, and suspend them all night from the outer branches of trees.

Cooling Vessels called *Alcurrazas*.

The Moors introduced into Spain a sort of unglazed earthen jugs, named *bucaros* or *alcurrazas*, which, being filled with water, present to the atmosphere a surface constantly humid, and furnish by evaporation, during the dry and hot weather, a refreshing beverage. The same practice has been adopted by degrees in various parts of the south of Europe. In India, during certain months, the apartments are kept comparatively cool, by dashing water against the matting of reeds or bamboos, which line the doors and the outside of the walls. Even the more luxurious mariners, in their voyages between the tropics, are accustomed to cool their wines, by lapping the bottle with wet flannel, and suspending it from the yard or under the cabin-windows. In all such cases, the effect is accelerated, though not augmented, by the swiftness of the current of air. What have been called *Egyptian coolers*, and lately produced by our potters, are less perfect in their operation. Being very thick, they require only to be soaked in water, and the evaporation from their

Cold. surface cools the adjacent air. On the inside, however, where the bottle is placed, the action, in consequence of the confined humidity, must be enfeebled. In damp weather, these vessels, it is evident, are entirely useless.

Indian Mode of Collecting Ice. The natives of India likewise are enabled, by directing a skilful process of evaporation, to procure for themselves a supply of ice, during their short winter. In the upper country, not far however from Calcutta, a large open plain being selected, three or four excavations are made in it about thirty feet square and two feet deep, and the bottom covered to the thickness of nearly a foot with sugar canes or dried stalks of Indian corn. On this bed are placed rows of small glazed earthen pans, about an inch and quarter deep, and extremely porous. In the dusk of the evening, during the months of December, January, and February, these are filled with soft water previously boiled, and suffered to cool, when the weather is very fine, and clear a great part of the water becomes frozen during the night. The pans are regularly visited at sunrise, and their contents thrown into baskets which retain the ice. These are now carried to a conservatory made by sinking a pit 14 or 15 feet deep, lined with straw under a layer of coarse blanketing. The small sheets of ice are thrown down into the cavity, and rammed into a solid mass. The mouth of the pit is then closed up with straw and blankets, and sheltered by a thatched roof.

Impressions Showered from a Clear Sky.

4. It was stated in the article CLIMATE, that impressions of cold are constantly showered down from a clear and azure sky. These effects are no doubt more conspicuous in the finer regions of the globe. Accordingly, they did not escape the observation of the ancients, but gave rise to opinions which were embodied in the language of poetry. The term *Ans* was applied only to the grosser part of the atmosphere, while the highest portion of it, free from clouds and vapour, and bordering on the pure fields of æther, received the kindred appellation of *Αἰθήρ*. But this word and its derivatives have always been associated with ideas of *cold*. We have seen that the verb *ἐξαιθρίζω* is used by Athenæus to signify, the cooling of a body, by exposure under a serene sky. Homer uses the term *Αἰθρῶς*, in speaking of the reception of his hero, when overcome with *cold* and toil.* The same poet of nature applies the epithet *Αἰθρηγένης* or *Αἰθρηγενέτης* or *frigidific*, to Boreas, the north wind.† The chorus in the *Antigone* of Sophocles deprecates the pelting storm, and likewise the cold (*αἰθέριος*) of inhospitable frozen tracts.‡ The word *αἰθρῶς* is employed by Herodotus to signify a chill as well as a dry atmosphere.|| Of the same import is the expression in Horace—*Sub Jove frigido*.

Cold. In the finer climates, especially, a transpiercing cold is therefore felt at night under the clear and sparkling canopy of heaven. The natives carefully avoid exposing themselves to this supposed celestial influence; yet a thin shed of palm-leaves may be made sufficient at once to screen them from the scorching rays of the sun, and to shelter them against the chilling impressions rained from the higher atmosphere. The captains of the French gallees in the Mediterranean, used formerly to cool their wine in summer, by hanging the flasks all night from the masts. At day-break, they were taken down and dipped in several kinds of fannel, to preserve them in the same state. The frigorific impression of a serene and azure sky, must undoubtedly have concurred with the power of evaporation, in augmenting the energy of the process of nocturnal cooling, practised anciently in Egypt, and now systematically pursued in the higher grounds of India. As the chillness accumulated on the ground is greatest in clear nights, when the moon shines brightest, it seemed very natural to impute this effect partly to some influence emanating from that feeble luminary. It was long imagined that the lunar beams are essentially cold; and some philosophers, at no remote period, have attempted even to prove this fact by experiment. Mr Boyle, though he rejected judicial astrology, was yet disposed to admit the notion of stellar influences.

The obvious mode of cooling water, or other liquids, by the infusion of ice or snow, was practised in the warmer countries from the earliest ages. It is even mentioned in the Proverbs of Solomon: "As the cold of snow in the time of harvest, so is a faithful messenger to them that send him." Aristotle, presuming that the finer parts of water are dissipated by congelation, maintained that it is pernicious to drink melted snow. This speculative opinion seems not, however, to have been regarded by the ancients. Theocritus calls snow-water an *ambrosial drink*,—*ποτὸς ἀμβροσίας*. Xenophon mentions the practice of cooling wine, by the addition of snow. It is related by the historians of Alexander the Great, that, in his Indian expedition, when he laid siege to the city of Petra, he commanded thirty pits to be dug and filled with snow, which was covered over with oak branches. The luxurious Romans had excavations regularly formed for keeping snow the whole year, chaff and other light substances being employed to preclude from it the access of heat. But, as the snow, preserved in this way, could not escape being soiled, instead of mixing it directly in the drinking cup, a more refined practice was introduced, of surrounding the silver goblet which contained the liquor with a mass of the melting snow. This improvement was ascribed to the profligate emperor Nero. Similar modes of storing up

^{Cold.} snow have been adopted in all the warm countries. The caves on the sides of Mount Atlas are considered as natural magazines, for supplying a material which is not only carried down to Palermo and Messina, but even shipped to the island of Malta. The Italians formerly cooled their wine, by setting the large glass flasks containing it, in wide vessels of wood or cork, the intervening space being filled with snow, on which water was poured.

th Saltpetre or nitre being almost a natural production of the east, its property of rendering water cold by solution, was probably known, from a very remote period, to the oriental nations. This process of cooling is described in the *Institutes* of Akbar as the discovery of that enlightened prince, who governed India with parental mildness, from the year 1560 to 1605. One part of nitre is directed to be thrown into a vessel containing two parts of water, and a gugglet of pewter or silver filled with pure water, and having its mouth close stopped, is then stirred quickly in the mixture for the space of a quarter of an hour.

^{Introduced into Italy.}

The frigorific property of nitre was probably first communicated from India or Persia to Europe, and seems to have become known to the Italians about the middle of the sixteenth century. As early as the year 1550, all the rich families in Rome cooled the liquors for their tables, by dissolving that salt in water. Into a vessel of cold water, the nitre was gradually added in the proportion of a fourth or fifth part, while a globular bottle, with a long neck, containing the wine or water to be cooled, was whirled rapidly round its axis. The salt, being afterwards recovered by crystallization, would always serve the same purpose again, with undiminished effect. In India, every family of distinction keeps a domestic, whose sole employment is to cool liquors by this process; but nitre, being cheap in that country, it is used in larger proportions, and the water charged with it is allowed to become a perquisite of the operator.

^{Cooling by Saline Powders.}

The application of salts to produce cold was extended by Boyle, and afterwards more successively by Fahrenheit. But, within these twenty years, Mr Walker of Oxford, and Professor Lowitz of St Petersburg, have resumed the subject, and produced compound saline powders, possessed of intense frigorific power. The solution of salts in water, expanding that liquid, augments its capacity for heat, and consequently depresses its temperature. This effect is likewise the greater, in proportion to the quantity of saline matter which can be dissolved. But after water is saturated with one species of salt, it can still absorb some portion of another. Hence the frigorific effects of solution are always increased, by employing a compound dry powder. Nitre and sal-ammoniac, or the nitrate of potash and the muriate of soda in equal parts, added in the form of a dry powder to three parts by weight of water, will sink Fahrenheit's thermometer 40 degrees. But equal parts of the muriate of ammonia and of the nitrate of potash, with one part and a half of the sulphate of soda or common Glauber's salt, will cool down three parts of water 46 degrees. A still greater effect, amounting

to 57 degrees, is produced, by dissolving equal parts of the nitrate of ammonia and of the carbonate of soda, in one part of water. The frigorific action is in general augmented, by throwing the desiccated powder into dilute acid instead of water. Thus, three parts of the phosphate of soda and two parts of the nitrate of ammonia joined to rather more than one part of weak nitric acid, will sink the thermometer 71 degrees.

^{Cold.}

These changes induced on the temperature of the liquid menstruum are, no doubt, considerable, yet they are still only transient, and the process requires some address and manipulation, not always readily attained. But the principle of evaporation, when rightly understood, leads to a far easier mode of cooling liquids, which may be prolonged at pleasure. A close investigation of that principle, at the very commencement of his philosophical labours, has conducted Professor Leslie through the whole train of his discoveries on the subject of refrigeration. The process of evaporation had not then been examined with attention. The depression of temperature which always accompanies it, was hastily supposed to be proportional to the rate with which the moisture is dissipated, and to be therefore augmented by every circumstance that can accelerate this effect. If water, contained in a porous vessel, expose on all sides its surface to a current of air, it will cool down to a certain point, and there its temperature will remain stationary. The rapidity of the current must, no doubt, hasten the period of equilibrium, but the degree of cold thus induced will be still the same. A little reflection may discover how this happens. Though the humid surface has ceased to grow colder, the dispersion of invisible vapour, and the corresponding abstraction of heat, still continues without intermission. The same medium, therefore, which transports the vapour, must also furnish the portion of heat required for its incessant formation. In fact, after the water has been once cooled down, each portion of the ambient air which comes to touch the evaporating surface must, from its contact with a substance so greatly denser than itself, be likewise cooled to the same standard, and must hence communicate to the liquid its surplus share of heat, or the difference between the prior and the subsequent state of the solvent, which is proportional to the diminution of temperature it has suffered. Every shell of air which encircles in succession the humid mass, while it absorbs, along with the moisture which it dissolves, the measure of heat necessary to convert this into steam, does, at the same instant, thus deposit an equal measure of its own heat, on the chill exhaling surface. The abstraction of heat by vaporization on the one hand, and, on the other, its deposition at the surface of contact, are, therefore, opposite contemporaneous acts, which soon produce a mutual balance, and thereafter the temperature induced continues without the smallest alteration. A rapid circulation of the evaporating medium may quicken the operation of those causes; but, so long as it possesses the same drying quality, it cannot, in any degree, derange the resulting temperature. The

^{Principle of Evaporation.}

Cold.

heat deposited by the air on the humid surface becomes thus an accurate measure of the heat spent in vaporizing the portion of moisture required for the saturation of that solvent at its lowered temperature. The dryness of the air is therefore, under all circumstances, precisely indicated, by the depression of temperature produced on a humid surface which has been exposed freely to its action.

Hygrometer.

Guided by these views, Mr Leslie was enabled to construct a correct *Hygrometer* that should indicate the dryness of the air, from the diminution of temperature which a small body of water, exposed on all sides, suffers by evaporation. His efforts again to improve this instrument, led him next to the invention of the *Differential Thermometer*, which was converted into an hygrometer, by having one of its balls covered with cambric, lint or tissue paper, capable of being easily wetted. Reduced to such a delicate and commodious form, it detected, with the utmost precision, and under all circumstances, the relative condition of the air in regard to dryness.

Cooling Effected by the Presence of Absorbents.

It appears that absorbent substances, exposing a broad surface, are capable of assimilating to their previous state the air confined over them. Flannel, for instance, which has been intensely dried, will support a remarkable degree of dryness in a close receiver. The trap-rock and compound clays, brayed into a coarse powder, and desiccated before a strong fire, will exert a more powerful and extended action. But dried oat-meal will act with equal energy, and for a longer time. Of the saline substances, the muriate of lime absorbs moisture with the greatest and most protracted force. After it has become drenched with humidity, it may likewise be recovered again, though the process of restoring it unaltered is rather troublesome. But the best and most powerful absorbent is the concentrated sulphuric acid, or the oil of vitriol of commerce, which continues for a long time to attract moisture with almost undiminished force, and possesses, besides, the valuable property, after it has become charged with humidity, of being easily restored again, by the application of heat, to its original strength.

Mode of Proceeding.

To cool water, in any climate or state of the atmosphere, we have only therefore to put it into a small porous vessel, presenting on all sides a humid surface, and to suspend this within a close wide cistern, of which the bottom is covered with a layer of sulphuric acid. The broad surface of the acid, absorbing the moisture as fast as it diffuses itself through the confined air, keeps that medium constantly at a point of extreme dryness, and thus enables it to support, with undiminished vigour, the process of evaporation.

In practice, the cistern or refrigeratory, having a broad cylindrical form, from twelve to sixteen inches in diameter, and composed of dense well-glazed earthenware (See Plate LXXV. fig. 7.), is placed in a cellar or other cool place, and charged with sulphuric acid to the height of about half an inch from the bottom. One of the porous earthen pots, being filled up to the lip with water fresh drawn from the well, is set upon a low porcelain stand in the middle of the cistern, to which the lid or cover is then care-

fully adapted. In the space of from three to perhaps five hours, the cooling is nearly completed, and the pot should now be removed: for though the water will be kept at the same degree of coldness as long as it remains shut up within the refrigeratory, the acid would be unnecessarily weakened by the incessant absorption of moisture.

Cold.

The production of cold is greater when the cistern is large, or when a small pot is used, inasmuch that the effect will be diminished one half, if the humid surface should equal that of the acid, the opposite actions of such surfaces inducing an exactly intermediate state, with respect to dryness and moisture, in the condition of the aerial medium. The power of evaporation is also diminished in the low temperatures. Thus, if the atmosphere were at 95°, by Fahrenheit, the water within the refrigeratory might be cooled down 36°, or brought to 59°; but if the thermometer be at 50° the water can be cooled only 18°, which brings it to the freezing point. This seems to be a very convenient property, since the power of the refrigeratory is always the greatest at the season when its application is most wanted.

It is easy, therefore, by such means, to cool water in our climate at all times, to near the freezing point, and, even under the torrid zone, to reduce it to the temperature of 60 degrees, which, in those regions, is sufficient perhaps for essential comfort.

By supplying a succession of porous earthen pots, the acid will continue to act with scarcely diminished force, till it has absorbed half its weight of moisture; during which time it will have assisted in cooling about fifty times that quantity of the water exposed to evaporation. At this stage, the dilute acid should be drawn off, and a charge of concentrated acid again introduced into the refrigeratory.

This method of procuring cold, it will readily be perceived, could be employed with advantage for various domestic purposes. For instance, butter may in summer be kept cool for the table, by putting it, after being washed with water, into a wet porous pot, and shutting this up for a couple of hours in the refrigeratory. To cool wine sufficiently, one bottle only is used at a time in the smallest refrigeratory: A sheath of stocking or flannel previously soaked in water being drawn over the body of the bottle, it is laid in a reclined position on one of the porcelain sliders, near the surface of the acid, and allowed to remain shut up during the space of three or four hours.

The refrigerating combination here employed produces its effect, by a sort of invisible distillation carried on by the play and circulation of the included air. The minute portions of moisture which successively combine with the contiguous medium, must abstract from the mass of water as much heat as would support them in the state of vapour, or would in ordinary cases convert them into steam. This vapour again, being conveyed through the air, is attracted by the sulphuric acid, and, recovering its liquid constitution, deposits the heat which it had borne away. The acid is therefore warmed at the expence of the water subjected to evaporation, and the whole performance of the apparatus consists in a mere transfer and interchange of condition.

Its Use to Domestic Purposes.

Cold.

CONGELATION

Congelation. Is the passage of any substance from the liquid to a solid form, in consequence of abstraction of heat. The conversion of water into ice could not fail to draw the notice of men in all ages. The minute and divided fragments of the same production, which descend from the clouds in the shape of snow or hail, displayed the various powers of nature. The ancients imagined, that water which has lain for ages in a frozen state acquires at last a permanent consolidation. They extended, accordingly, the name of ice (*κρυσάλλος*, or *crystal*) to the pure and pellucid kind of quartz, which often occurs on the sides of lofty mountains, near the boundary of perpetual congelation.

After 10
An in

It was early remarked that melted ice has the lightness and quality of boiled water. In fact, the portion of air combined with ordinary water is discharged in the act of freezing as well as in that of boiling. Water thus deprived of its air, is therefore prepared for a readier congelation. The ancients accordingly, we have seen, always boiled the water which they designed afterwards to cool. Aristotle relates in his *Meteorology*, that the fishermen who cast their nets in the Pontine Lake, used to carry in close vessels boiled water, for the purpose of sprinkling the reeds, that these might quickly freeze together, and cease to disturb the fish by their rustling noise. The expulsion of air from water during the progress of congelation, was afterwards fully proved by Mariotte, one of the earliest members of the French Academy of Sciences. If two wine glasses, filled, the one with water from the well, and the other with water recently boiled, be exposed to the frost, the ice of the latter will seem almost uniformly pellucid, while the ice of the former will appear charged with small air-bubbles crowding towards the centre of the mass, to which they are driven by the advance of the congelation.

That congelation shoots at angles of 120 degrees, was first observed in the beginning of the seventeenth century by the great Kepler; and this ardent and inventive genius, in an elaborate Dissertation, which he printed as a New Year's present, investigated the various forms and modifications of the icy crystals. The subject was next discussed by Des Cartes and Bartholinus, and about a century afterwards resumed by Mairan, and may be considered as a step towards the general theory of crystallography, which has been since reared by the patience and ingenuity of Häuy.

Imperfect
Congelation.

Other liquids, such as vinegar, dilute mineral acids, weak spirits, and saline solutions, are likewise capable of being frozen; but they yield an ice distinctly different from that of pure water, resembling an aggregation rather than an uniform solid, and wanting consistency, strength, and clearness. The frost appears to seize on the water only, and to fill the compound liquid with close spicular shoots, entangling the stronger acid or brine in their interstices. It was a mistake, therefore, to assert that the ice of sea-water is really fresh. In the process of melting, some portion of the brine may probably flow off, but

the residue still is always brackish. This fact is even positively stated by the missionary Crantz, in his accurate account of Greenland. The very intelligent and enterprising navigator, Mr Scoresby, reckons the specific gravity of the spongy salt-water ice to be .873, while that of fresh-water ice amounted to .937.

Cold.

The ancients were altogether unacquainted with artificial congelation, and with any cold, indeed, below that of freezing. The application of nitre to the cooling of water seems, before the close of the sixteenth century, to have suggested to the Italians the experiment of mixing it with snow. A very intense degree of cold was thus generated, capable of converting speedily into solid ice a body of water contained in a smaller vessel immersed in the dissolving mixture. Sanctorio, who may be regarded as the father of modern physics, mentions, in his *Commentary on Avicenna*, that he produced the same effect, by employing common salt instead of nitre, in the proportion of the third part of the snow, and had repeatedly performed the experiment in the presence of a numerous auditory.

Artificial
Congelation
discovered
in Italy:

From Italy, this discovery was gradually communicated over the rest of Europe. In the course of the seventeenth century, iced creams, fruits, and various confections, were first produced on the tables of the luxurious. The famous coffee-house, *Procope*, was founded at Paris in 1660, by a Florentine of that name, a vender of lemonade, who was very successful in the art of preparing rich ices. Thirty years afterwards, the use of such artificial delicacies in that city had become quite common.

The cold resulting from the addition of saline powders to snow or pounded ice, depends on the powerful attraction of those salts which restores the frozen mass to its liquid form, and therefore augments its capacity for heat. Fahrenheit fixed the commencement of his thermometrical scale at the temperature of the compound of salt and snow, conceiving it to be the lowest possible. But much lower degrees of cold are now produced. One part of the muriate of soda, or purified common salt, being added to two parts of dry snow or pounded ice, will sink the thermometer five degrees below zero. One part of sal-ammoniac, and two of common salt, joined to five parts of snow, will bring it seven degrees lower. But equal parts of the nitrate of ammonia and common salt, joined to two parts and a half of snow, will depress the thermometer 25 degrees below the freezing point.

Rendered
more In-
tense.

Still more intense cold might be produced, if the ingredients were, before their mixture, cooled down to congelation. Thus, five parts of the muriate of lime, added to four parts of snow, will sink the thermometer to 40 degrees below the beginning of the scale, or the limit of freezing mercury; and, if the muriate of lime were crystallized, the effect would be 10 degrees more. The same extreme energy is exerted, on adding four parts of dry caustic potash to three parts of snow.

Cold.

The mineral acids likewise, in a diluted state, produce similar effects. Two parts of weak sulphuric acid, joined to three of snow, will sink the thermometer to 23 degrees below zero. The muriatic and nitric acids, in nearly the same proportions, will depress it from 4 to 7 degrees more. By repeating the applications, therefore, a most intense cold may be created. Yet, to succeed completely, a skilful manipulation is required. The saline matters should be reduced to a fine powder, and the freezing mixtures should be made in very thin vessels, not larger than they barely hold them. In this way, by successive applications of cooling, Mr Walker once obtained the enormous cold of 91 degrees below the commencement of Fahrenheit's scale.

The mere evaporation of some very volatile liquids is sufficient to produce excessive cold. Thus, if a thermometer, having its bulb covered with lint, be dipped in the common or sulphuric ether, it will, on exposure to the air, sink perhaps 30 or 40 degrees. This effect is augmented under the receiver of an air-pump. If a narrow thin tube of glass, filled with water, and cased on the outside with lint soaked in ether, be suspended above the pump, and the exhaustion quickly made, a cylinder of ice will be formed.

The same property is manifested in a higher degree by a singular liquid, discovered by Lampadius in 1796, by distilling a mixture of pyrites and charcoal. It was called at first the *alcohol of sulphur*, but now more appropriately the *sulphuret of carbon*. According to Dr Marcet, who has completed the investigation of its properties, a thermometer having its bulb covered with lint wetted by this liquid, and held in the open air, will sink not fewer than 60 degrees. But if the same experiment be performed within the exhausted receiver of an air-pump, the alcohol of the barometer will even descend to 82 degrees below zero. It must be observed, however, that these effects produced by the evaporation of ether, and of the sulphuret of carbon, are quite evanescent, and that the receiver becomes soon charged with their fumes, which then prevent any farther action. Those fumes likewise corrode the valves of the pump, and soon render it quite useless. Neither ether, therefore, nor the sulphuret of carbon, could be applied in practice with any sort of advantage, to the production of ice, even on the smallest scale.

New Mode
of Artificial
Congelation.

We have now to relate a discovery which will enable human skill to command the refrigerating powers of nature; and, by the help of an adequate machinery, to create cold and produce ice, on a large scale, at all seasons, and in the hottest climates of the globe. But, to explain this interesting subject with greater clearness and accuracy, it is requisite to trace the successive advances which conducted to the result. Where a conclusion appears simple, the careless observer is apt to suppose it easily attained; yet, though sound philosophy tends always to simplification, the rare quality of simplicity is scarcely ever the flush of intuition, but the slow fruit of close and patient investigation.

In pursuing the researches with his hygrometer, Professor Leslie was early induced to inquire into the condition of the higher atmosphere, and its relations

to humidity. He thus detected a fact of great importance in meteorology, and pointing at various ulterior views.

Cold.

As rarefaction enlarges the capacity of air for heat, so it likewise augments the disposition to hold moisture; at the same time, that the removal of the ordinary pressure facilitates the expansion of the liquid matter, and its conversion into a gaseous form. Accordingly, if the hygrometer be suspended within a large receiver, from which a certain portion of air is quickly abstracted, it will sink with rapidity. In summer, the additional dryness thus produced amounts to about 50 hygienic degrees, each time the air has its rarefaction doubled; so that, supposing the operation of exhausting to be performed with expedition, and the residuum reduced to a sixty-fourth part, the hygrometer would mark a descent of 300°. But this effect is only momentary, for the thin air very soon becomes charged with moisture, and, consequently, ceases to act on the wet ball of the hygrometer. The cold, however, excited on the surface of that ball, by such intense evaporation, will have previously frozen the coating.

The increased power of aqueous solution which air acquires as it grows thinner, being ascertained and carefully investigated, the object was to combine the action of absorbent with the transient dryness produced within a receiver by rarefaction. The sentient ball of the hygrometer being covered with dry salt of tartar, the instrument first indicated increasing dryness, and afterwards, as the rarefaction proceeded, it changed its course, and marked humidity. The same variation of effect nearly was observed, when the hygrometer had been wetted as usual with pure water, and a broad saucer containing the mild vegetable alkali was placed on the plate of the air-pump. It was thus proved, that the action of this imperfect absorbent is soon overpowered by the tendency to vaporization in attenuated air, and that, beyond a certain limit, it surrenders its latent moisture.

Mr Leslie resolved, therefore, to try the effect of sulphuric acid, whose peculiar energy as an absorbent he had, under other circumstances, already ascertained. But various incidents prevented him, for a considerable time, from resuming his philosophical inquiries. At last he began those projected experiments, and was almost immediately rewarded by the disclosure of a property, the application of which blazed on his fancy. In the month of June 1810, having introduced a surface of sulphuric acid under the receiver of an air-pump, he perceived with pleasure that this substance only superadded its peculiar attraction for moisture, to the ordinary effects resulting from the progress of exhaustion; and, what was still more important, that it continued to support, with undiminished energy, the dryness thus created. The attenuated air was not suffered, as before, to grow charged with humidity; but each portion of that medium, as fast as it became saturated by touching the wet ball of the hygrometer, transported its vapour to the acid, and was thence sent back denuded of the load, and fitted again to renew its attack with fresh vigour. By this perpetual circulation, therefore, between the exhaling and the absorbing surface, the diffuse residuum of air

Cold. is maintained constantly at the same state of dryness. The sentient ball of the hygrometer, which had been covered with several folds of wetted tissue paper, was observed, at an early stage of the operation, suddenly to lose its blue tint and assume a dull white, while the coloured liquor sprung upwards in the stem, where it continued, for the space of a minute, stationary, and again slowly subsided. The act of congelation had, therefore, at this moment taken place, and the paper remained frozen several minutes, till its congealed moisture was entirely dispersed. Pursuing this decisive intimation, the hygrometer was removed, and a watch-glass filled with water substituted in its place. By a few strokes of the pump, the whole was converted into a solid cake of ice, which, being left in the rare medium, continued to evaporate, and, after the interval of perhaps an hour, totally disappeared. A small cup for holding the water was next adopted, and the whole apparatus gradually enlarged.

Efficient
Power nearly
the same
at all Tem-
peratures.

The powers, both of vaporization and of absorption, being greatly augmented in the higher temperatures, the same limit of cold nearly is in all cases attained, by a certain measure of exhaustion. When the air has been rarefied 250 times, the utmost that, under such circumstances, can perhaps be effected, the surface of evaporation is cooled down 120 degrees of Fahrenheit in winter, and would probably sink near 200 in summer. Nay, a far less tenuity of the medium, when combined with the action of sulphuric acid, is capable of producing and supporting a very intense cold. If the air be rarefied only 50 times, a depression of temperature will be produced, amounting to 80 or even 100 degrees of Fahrenheit's scale.

Mode of
Proceeding.

We are thus enabled, in the hottest weather, to freeze a mass of water, and to keep it frozen, till it gradually wastes away, by a continued but invisible process of evaporation. The only thing required is, that the surface of the acid should approach tolerably near to that of the water, and should have a greater extent, for otherwise the moisture would exhale more copiously than it could be transferred and absorbed, and, consequently, the dryness of the rarefied medium would become reduced, and its evaporating energy essentially impaired. The acid should be poured to the depth perhaps of half an inch in a broad flat dish, which is covered by a receiver of a form nearly hemispherical; the water exposed to congelation may be contained in a shallow cup, about half the width of the dish, and having its rim supported by a narrow porcelain ring upheld above the surface of the acid by three slender feet. (See fig. 1 and 2. Plate LXV.) It is of consequence that the water should be insulated as much as possible, or should present only a humid surface to the contact of the surrounding medium, for the dry sides of the cup might receive, from communication with the external air, such accessions of heat, as greatly to diminish, if not to counteract the refrigerating effects of evaporation. This inconvenience, however, is in a great measure obviated, by investing the cup with an outer case at the interval of about half an inch. If both the cup and its case consist of glass, the process of congelation is viewed most completely; yet when they are formed of a bright metal, the effect

appears on the whole more striking. But the preferable mode, and that which prevents any waste of the powers of refrigeration, is to expose the water in a pan of porous earthen-ware. If common water be used it will evolve air bubbles very copiously as the exhaustion proceeds; in a few minutes, and long before the limit of rarefaction has been attained, the icy spicule will shoot beautifully through the liquid mass, and entwine it with a reticulated contexture. As the process of congelation goes forward, a new discharge of air from the substance of the water takes place, and marks the regular advances of consolidation. But after the water has all become solid ice, which, unless it exceed the depth of an inch, may generally be effected in less than half an hour, the circle of evaporation and subsequent absorption is still maintained. A minute film of ice, abstracting from the internal mass a redoubled share of heat, passes, by invisible transitions, successively into the state of water and of steam, which, dissolving in the thin ambient air, is conveyed to the acid, where it again assumes the liquid form, and, in the act of combination, likewise surrenders its heat.

Cold.

In performing this experiment, the object is generally to seek at first to push the rarefaction as far as the circumstances will admit. But the disposition of the water to fill the receiver with vapour, being only in part subdued by the action of the sulphuric acid, a limit is soon opposed to the progress of exhaustion, and the included air can seldom be rarefied above a hundred times, or till its elasticity can support no more than a column of mercury about three tenths of an inch in height. A smaller rarefaction, perhaps from ten times to twenty times, will be found sufficient to support congelation after it has once taken place. The ice then becomes rounded by degrees at the edges, and wastes away insensibly, its surface being incessantly corroded by the play of the ambient air, and the minute exhalations conveyed by an invisible process to the sulphuric acid, which, from its absorbing the vapour, is all the time maintained above the temperature of the apartment. The ice, kept in this way, suffers a very slow consumption; for a lump of it, about a pound in weight and two inches thick, is sometimes not entirely gone in the space of eight or ten days. During the whole progress of its wasting, the ice still commonly retains an uniform transparent consistence; but, in a more advanced stage, it occasionally betrays a sort of honey combed appearance, owing to the minute cavities formed by globules of air, set loose in the act of freezing, yet entangled in the mass, and which are afterwards enlarged by the erosion of the solvent medium.

Moderate
Rarefaction
sufficient to
maintain the
Ice.

But almost every practical object is attained, through far inferior powers of refrigeration. Water is the most easily frozen, by leaving it, perhaps for the space of an hour, to the slow action of air that has been rarefied only in a very moderate degree. This process meets with less impediment, and the ice formed by it appears likewise more compact, when the water has been already purged of the greater part of its combined air, either by distillation or by long continued boiling. The water which has undergone such operation, should be introduced as

Cold.

quickly as possible into a decanter, and filled up close to the stopper, else it will attract air most greedily, and return nearly to its former state in the course of a few hours.

Elegant
Mode of
Freezing.

The most elegant and instructive mode of effecting artificial congelation, is to perform the process under the transfer of an air-pump. A thick but clear glass cup being selected, of about two or three inches in diameter, has its lips ground flat, and covered occasionally, though not absolutely shut, with a broad circular lid of plate glass, which is suspended horizontally from a rod passing through a collar of leather. (See fig. 6. Plate LXV.) This cup is nearly filled with fresh distilled water, and supported by a slender metallic ring, with glass feet, about an inch above the surface of a body of sulphuric acid, perhaps three quarters of an inch in thickness, and occupying the bottom of a deep glass basin that has a diameter of nearly seven inches. In this state, the receiver being adapted, and the lid pressed down to cover the mouth of the cup, the transferer is screwed to the air-pump, and the rarefaction, under those circumstances, pushed so far as to leave only about the hundred and fiftieth part of a residuum; and the cork being turned to secure that exhaustion, the compound apparatus is then detached from the pump, and removed to some convenient apartment. As long as the cup is covered, the water will remain quite unaltered; but, on drawing up the rod half an inch or more, to admit the play of the rare medium, a bundle of spicular ice will, after the lapse perhaps of five minutes, dart suddenly through the whole of the liquid mass; and the consolidation will afterwards descend regularly, thickening the horizontal stratum by insensible gradations, and forming in its progress a beautiful transparent cake. On letting down the cover again, the process of evaporation being now checked or almost entirely stopped, the ice returns slowly into its former liquid condition. In this way, the same portion of water may, even at distant intervals of time, be repeatedly congealed and thawed successively twenty or thirty times. During the first operations of freezing, some air is liberated; but this extrication diminishes at each subsequent act, and the ice, free from the smallest specks, resembles a piece of the purest crystal.

Progress of
Congelation.

This artificial freezing of water in a cup of glass or metal, affords the best opportunity of examining the progress of crystallization. The appearance presented, however, is extremely various. When the frigorific action is most intense, the congelation sweeps at once over the whole surface of the water, obscuring it like a cloud. But, in general, the process advances more slowly; bundles of spicular, from different points, sometimes from the centre, though commonly from the sides of the cup, stretching out and spreading by degrees with a sort of feathered texture. (See fig. 4.) By this combined operation, the surface of the water soon becomes an uniform sheet of ice. Yet the effect is at times singularly varied; the spicular shoots, advancing in different directions, come to inclose, near the middle of the cup, a rectilinear space, which, by unequal though continued encroachment, is reduced to a triangle; and the mass below, being partly frozen and therefore expanded, the water is gradually squeezed up through the orifice,

and forms by congelation a regular pyramid, rising by successive steps; or, if the projecting force be greater, and the hole more contracted, it will dart off like a pillar. The radiating or feathered lines which at first mark the frozen surface, are only the edges of very thin plates of ice, implanted at determinate angles, but each parcel composed of parallel planes. This internal formation appears very conspicuous in the congealed mass which has been removed from a metallic cup, before it is entirely consolidated.—Sea-water will freeze with almost equal ease, but it forms an incompact ice like congealed syrup, or what is commonly called *water-ice*.

Cold.

When cups of glass or metal are used, the cold excited at the open surface of the liquid extends its influence gradually downwards. But if the water be exposed in a porous vessel, the process of evaporation, then taking effect on all sides, proceeds with a nearly regular consolidation towards the centre of the mass, thickening rather faster at the bottom from its proximity to the action of the absorbent, and leaving sometimes a reticulated space near the middle of the upper surface, through which the air, disengaged by the progress of congelation, makes its escape.

When very feeble powers of refrigeration are employed, a most singular and beautiful appearance is, in course of time, slowly produced. If a pan of porous earthen ware, from four to six inches wide, be filled to the utmost with common water till it rise above the lips, and planted above a dish of ten or twelve inches diameter, containing a body of sulphuric acid, and then a broad round receiver placed over it; on reducing the included air to some limit between the twentieth and the fifth part of its usual density, according to the coldness of the apartment, the liquid mass will, in the space of an hour or two, become entwined with icy shoots, which gradually enlarge and acquire more solidity, but always leave the fabric loose and unfrozen below. The icy crust which covers the rim, now receiving continual accessions from beneath, rises perpendicularly by insensible degrees. From each point on the rough surface of the vessel, filaments of ice, like bundles of spun glass, are protruded, fed by the humidity conveyed through its substance, and forming in their aggregation a fine silvery surface, analogous to that of fibrous gypsum or satin-spar. At the same time, another similar growth, though of less extent, takes place on the under side of the pan, so that continuous icy threads might appear vertically to transpire the ware. The whole of the bottom becomes likewise covered over with elegant icy foliations. (See fig. 5.) Twenty or thirty hours may be required to produce those singular effects; but the upper body of ice continues to rise for the space of several days, till it forms a circular wall of near three inches in height, leaving an interior grotto lined with fantastic groupes of icicles. In the meanwhile, the exfoliations have disappeared from the under side, and the outer incrustation is reduced, by the absorbing process, to a narrow ring. The icy wall now suffers a regular waste from external erosion, and its fibrous structure becomes rounded and less apparent. Of its altitude, however, it loses but little for some time; and even a deposition of congealed films along its coping or upper edge, seems to take place, at a certain stage of the process.

Cold.

This curious effect is owing to a circumstance, which as it serves to explain some of the grand productions of nature, particularly the *Icebergs of the Arctic Circle*, merits particular attention. The circular margin of the ice, being nearer the action of the sulphuric acid than its inner cavity, must suffer, by direct evaporation, a greater loss of heat; and, consequently, each portion of thin air that rises from the low cavity, being chilled in passing over the colder ledge, must deposit a minute corresponding share of its moisture, which instantly attaches itself and incrusts the ring. - Whatever inequalities existed at first in the surface of the ice, will hence continually increase.

Artificial
Congelation
formed on a
large Scale.

Artificial congelation is always most commodiously performed on a large scale. Since the extreme of rarefaction is not wanted, the air pump employed in the process admits of being considerably simplified, and rendered vastly more expeditious in its operation: Two or three minutes at most will be sufficient for procuring the degree of exhaustion required, and the combined powers of evaporation and absorption will afterwards gradually produce their capital effect. In general, plates of about a foot in diameter should be preferred, which can be connected at pleasure with the main body of the pump. The dish holding the sulphuric acid is nearly as wide as the flat receiver; and a set of evaporating pans belongs to it, of different sizes, from seven to three inches in diameter, which are severally to be used according to circumstances. The largest pan is employed in the cold season, and the smaller ones may be successively taken as the season becomes sultry. On the whole, it is better not to overstrain the operation, and rather to divide the water under different receivers, if unusual powers of refrigeration should be required. As soon as the air is partly extracted from one receiver, the communication is immediately stopped with the barrel of the pump, and the process of exhaustion is repeated on another. In this way, any number of receivers, it is evident, may be connected with the same machine. If we suppose but six of these to be used, the labour of a quarter of an hour will set as many evaporating pans in full action, and may, therefore, in less than an hour afterwards produce nearly six pounds of solid ice. The waste which the water sustains during this conversion is extremely small, seldom indeed amounting to the fiftieth part of the whole. Nor, till after multiplied repetitions, is the action of the sulphuric acid considerably enfeebled by its aqueous absorption. At first that diminution is hardly perceptible, not being the hundredth part when the acid has acquired as much as the tenth of its weight of water. But such influence gains rapidly, and rises with accelerated progression. When the quantity of moisture absorbed amounts to the fourth part by weight of the acid, the power of supporting cold is diminished by a twentieth; and, after the weights of both these come to be equal, the refrigerating energy is reduced to less than the half. Sulphuric acid is hence capable of effecting the congelation of more than twenty times its weight of water, before it has infused near an equal bulk of that liquid, or has lost about the eighth part of its refrigerating power. The acid should then be removed, and concentrated anew by slow distillation.

Cold.

Congelation
might be
connected
with the
Steam-Engine.

When the exhaling and absorbing surfaces are rightly disposed and apportioned, the moderate rarefaction, from twenty to forty times, which is adequate to the freezing of water, may be readily procured by the condensation of steam. In all manufactures where the steam-engine is employed, ice may, therefore, at all times be formed in any quantity, and with very little additional expence. It is only required to bring a narrow pipe from the condensing vessel, and to direct it along a range of receivers, under each of which the water and the acid are severally placed. These receivers, with which the pipe communicates by distinct apertures, may, for the sake of economy, be constructed of cast-iron, and adapted with hinges to the rim of a broad shallow dish of the same metal, but lined with lead to hold the acid.

The combined powers of rarefaction and absorption are capable of generating much greater effects than the mere freezing of water. Such frigorific energy, however, is at all times sufficient for effecting the congelation of mercury. Accordingly, if mercury, contained in a hollow pear-shaped piece of ice, be suspended by cross threads near a broad surface of sulphuric acid under a receiver; on urging the rarefaction, it will become frozen, and may remain in that solid state for the space of several hours. But this very striking experiment is easily performed without any foreign aid. Having introduced mercury into the large bulb of a thermometer, and attached the tube to the rod of a transferrer, let this be placed over the wide dish containing sulphuric acid, in the midst of which is planted a very small tumbler nearly filled with water: After the included air has been rarefied about fifty times, let the bulb be dipped repeatedly into the very cold but unfrozen water, and again drawn up about an inch; in this way, it will become incrustated with successive coats of ice, to the thickness perhaps of the twentieth part of an inch: The water being now removed, the pendant icicle cut away from the bulb, and its surface smoothed by the touch of a warm finger, the transferrer is again replaced, the bulb let down within half an inch of the acid, and the exhaustion pushed to the utmost: When the syphon-gage has come to stand under the tenth of an inch, the icy crust starts into divided fissures, and the mercury, having gradually descended in the tube till it reach its point of congelation, or 39 degrees below zero, sinks by a sudden contraction almost into the cavity of the bulb; and the apparatus being then removed and the ball broken, the metal appears a solid shining mass, that will bear the stroke of a hammer.

Still greater
Cold created.

But a still greater degree of cold may be created, by applying the same process likewise to cool the atmosphere which encircles the apparatus itself. A glass matrass was blown nearly of a hemispherical shape, its bottom quite flat, and about three inches in diameter, and its neck about half an inch wide and cut square over: The whole was covered with a coat of patent lint, which takes up water very copiously, a portion of sulphuric acid was next introduced, forming a layer of perhaps a quarter of an inch thick, and a spirit of wine thermometer, having its bulb also cased with wetted lint, was then inserted within the matrass, a brass ring attached to the tube securing it in the

Cold.

right position. Things being thus arranged, the mattress or flat bottle, with its thermometer, was placed on a slender stool with glass feet, about an inch above the sulphuric acid in the broad bason, and the large receiver luted over it. The air was then partly extracted, till the gage came below one inch: In a few minutes, the lint was frozen entirely, and looked white. After an interval of a quarter of an hour, to allow time for the evaporation of that icy coat to cool down the interior apparatus, the pump was again urged, and the exhaustion pushed to about three-tenths of an inch. In a short while, the inclosed thermometer sunk not fewer than 180 degrees, and remained stationary, till the ice had wasted away.

It is obvious, therefore, that the refrigerating powers could be pushed still farther by a judicious combination of the apparatus. An idea of the mode of proceeding may be formed from the inspection of figure 8. It would be easy to show, that the maximum effect is obtained, when the dimensions of the successive cases rise in a geometrical progression. The action, however, is not doubled for each additional case, but increased rather more than one-half.

Simpler
Mode of
Congelation;

These plans are difficult in the execution, and though they enlarge our conceptions of the extent of the descending scale of heat, yet they furnish merely speculative results. A very important practical improvement has been lately made in the process of artificial congelation. Sulphuric acid is certainly a cheap and most powerful agent of absorption; but the danger in using such a corrosive liquid, especially by unskilful persons, formed always

a serious obstacle to its general adoption. Mr Leslie had early noticed the remarkable absorbent quality of our mouldering whinstone or porphyritic trap; and, in April 1817, he substituted that material, grossly pounded and dried before a kitchen fire, instead of sulphuric acid, and actually froze a body of water with great facility. This earth will attract the fiftieth part of its weight of moisture before its absorbent power is reduced to the one half, and is hence capable of freezing the sixth part of its weight of water. It may be repeatedly dried, and will, after each operation, act with the same energy as at first.

Cold.

by dry
Pounded
Whinstone.

But an absorbent still more convenient and powerful has since occurred to Mr Leslie;—it is merely parched oatmeal. With a body of oatmeal of a foot in diameter, and rather more than an inch deep, he froze a pound and a quarter of water, contained in a hemispherical porous cup. The meal is easily dried and restored again to its action. In a hot climate, the exposure to the sun alone might prove sufficient. By the help of this simple material, therefore, ice will be easily and safely produced in any climate, and even at sea.

or Parched
Oatmeal.

Other substances could, no doubt, be employed as absorbents. But, except the muriate of lime, or what is called the oil of salt desiccated, none hold out any prospect of success. Dried common salt will barely effect congelation; and stucco, or the sulphate of lime, deprived of its water of crystallization, which might seem to promise a powerful absorption, has scarcely any efficacy whatever. (D.)

EXPLANATION OF PLATE LXV.

Fig. 1. Represents a large air-pump intended for the purpose of freezing water, consisting of six receivers, each of them having a broad glass saucer for holding sulphuric acid, and a small porous earthen cup containing the water.

Fig. 2. A section of the above, showing the communication between the receivers and the body of the pump.

Fig. 3. The lever key, for opening and shutting the cocks.

Fig. 4. The more ordinary appearance of the surface of the water in the porous cup, at the moment when the act of congelation begins.

Fig. 5. The very singular kind of ice, striated, columnar, and cavernous, which, under a slight rarefaction, but in cold weather, rises slowly and changes its form by degrees, while part of the remaining water is drawn through the substance of the cup, and covers the outside with a thick icy collar above those irregular foliations.

Fig. 6. Represents an elegant mode of almost instantaneously freezing within a transferrer; above the saucer of the sulphuric acid, is placed a glass cup holding water, and the air having been previously exhausted, and the instrument detached from the pump, on pulling up the rod, the water, now left ex-

posed to the most powerful evaporation, quickly runs into spicular ice, which gradually increases and consolidates into a pure transparent mass. The lid being let down again upon the glass cup, the action ceases, and the ice returns slowly to the state of water.

Fig. 7. A refrigeratory for cooling water at all times to a moderate degree, without the operation of an air-pump; a body of sulphuric acid lying at the bottom of the pan, while a porous vessel containing water is set in the centre of the refrigeratory, and the air is confined about it by replacing the lid.

Fig. 8. Exhibits a system of vessels for producing spontaneously great cold. It consists of a series of leaden or pewter vessels, placed one within the other, and whose surfaces form a descending geometrical progression, being covered externally with soft wet lint, and holding each of them a portion of sulphuric acid. The powerful evaporation maintained by this arrangement causes the interior vessels to become successively colder, and thus augments, by a repeated multiplication, the final effect. Placed under the receiver of the air-pump, this system of evaporating vessels, with no very high degree of exhaustion, and at all seasons, excites ultimately the most intense cold yet produced, far exceeding what is required for the congelation of mercury.

A number of the machines here described have been constructed, under the direction of the inventor, by Mr Cury, Optician, London, and sent to various parts of the Globe. It is only to be regretted, that the demand has not been sufficient for establishing a manufactory of them, which, by greatly reducing the cost, would encourage their general introduction.

COLONY.

Colony.
Definition.

THE term *Colony* has not been used with much precision. Dr Johnson defines it, "A body of people drawn from the mother country to inhabit some distant place;" and it would not be easy to find a short expression better calculated to embrace all the particulars to which, at any time, the term is applied. Yet this will be found to include some very heterogeneous objects; and, what is more, to express particulars to which the term *Colony* really does not extend. When the French Protestants, for example, settled, in great numbers, in England, and in the United Provinces, they were "a body of people drawn from the mother country to inhabit a distant place," but did not, for that reason, become a colony of France. Let the first part of the definition be supposed to be correct, and that a colony must, of necessity, be "a body of people drawn from the mother country;" something more is necessary to complete the definition, than the idea of inhabiting a distant place; for not every sort of inhabiting constitutes them a colony.

It seems necessary that, inhabiting a distant place, they should not come under the authority of any foreign government, but either remain under the government of the mother country, or exist under a government of their own. Of colonies remaining under the government of the mother country, the West India islands of the different European states afford an example. Of those existing under a government of their own, the most celebrated example is found in the colonies of the ancient states of Greece. The United States of America, as they constituted an example of colonies of the first sort, before the revolution which disjoined them from the mother country, so they may be regarded as constituting an example of colonies of the Grecian sort, now that they exist under a government of their own; though our resentment at their preferring to live under a government of their own, has prevented us from regarding them in the endearing light of a colony, or daughter country—has made us much rather apply to them the name of enemies—and our feelings towards them, to possess a greater share of those of the hostile, than of those of the amicable sort.

Again, however, the term *Colony* is sometimes employed in a sense in which the idea of a body of people, drawn from the mother country, hardly seems to be included. Thus, we talk of the British colonies in the east, meaning, by that mode of expression, the East Indies. Yet it can hardly be said, that any body of people is drawn from the mother country to inhabit the East Indies. There is nobody drawn to inhabit, in the proper sense of the word. A small number of persons, such as are sent to hold possession of a conquered country, go; and, in this sense, all the conquered provinces of the ancient

VOL. III. PART I.

Roman empire might be called, what they never have been called, colonies of Rome.

Colony.

In the meaning of the term *Colony*, the predominant idea among the ancient Greeks and Romans, appears to have been that of the *people*,—the going out of a body of people to a new and permanent abode. Among the moderns, the predominant idea appears to be that of the *territory*,—the possession of an outlying territory; and, in a loose way of speaking, almost any outlying possession, if the idea of permanency is united, would receive the name of a colony. If we use the term with so much latitude as to embrace the predominating idea both of ancients and moderns, we shall say that a colony means an outlying part of the population of the mother country, or an outlying territory belonging to it; either both in conjunction, or any one of the two by itself.

We shall first treat of that class of them in the conception of which the idea of the people is the predominating idea. Of this sort were the Roman and the Grecian colonies, and of this sort are some of the British colonies.

The Roman colonies arose out of a peculiarity in the situation of the Roman people. In that, as in other countries, the lands were originally regarded as belonging to the state; and as belonging to the people, when the people took the powers of government to themselves. A sense of convenience, there, as everywhere else, rendered the land private property by degrees; and, under a form of government so very defective as the Roman, the influence of the leading men enabled them, in a short time, to engross it. The people, when reduced to misery, did not altogether forget, that the land had once been regarded as theirs; and every now and then, asserted their claims in so formidable a manner, that, when aided by circumstances, they compelled the ruling few to make something of a sacrifice. They did not, indeed, compel them to give up the lands which they had themselves appropriated, but it always happened, that in the countries conquered by the Romans, a portion of the lands was public property, and continued to be cultivated for the benefit of the Roman state. When the importunity of the people for a division of lands began to be troublesome or formidable, a portion of these lands was generally resorted to, enough to take off the most fiery of the spirits, and contenting the leaders, to quiet the populace for a time. The portion of land set apart for the purpose was divided, at the rate of so much for every man; and a sufficient number of persons to occupy it, and to form a community, were sent out, more or less provided with the various supplies which were necessary for commencing the settlement.

In the nature of an establishment of this descrip-

. K K

Colony.

tion there is no mystery, and hardly anything which requires explanation. The colonists lived in a Roman province, under Roman laws, and differed not materially from the people of any other local jurisdiction. Being once got rid of, no farther advantage was expected from them than from the other inhabitants of the country, in paying taxes for example, and furnishing men for the army. In some few instances, some benefit in the way of defence was looked to in the planting of colonies, when they were established in newly conquered countries, the people of which were not yet patient under the yoke, or when they were placed in the way of invading enemies. But not much advantage of this sort can be derived from a colony, which in general has more need to receive than ability to yield protection.

These colonies were planted wholly for the benefit of the Roman aristocracy. They were expedients for preserving to them the extraordinary advantages and powers they had been enabled to assume, by allying that impatience of the people under which the retention of them became difficult and doubtful. The wonder is, that the people were so easily contented, and having certain means of intimidating the aristocracy to so great a degree, they did not insist upon greater advantages. And the pity is, that they understood so little what was for their advantage. If, instead of demanding a portion of land, the benefit of which, at best, was only temporary, they had demanded good laws, and had obtained efficient securities for good government, securities against that prevalence of the interests of the few over the interests of the many which existed to so great an extent in the Roman government, as it has existed and still does exist in almost all other governments, they would have done themselves, and they would have done the human race, the greatest of all possible services. But the progress of the human mind was then too small to enable it to see distinctly what was the real object of good government, or what the means which would be effectual in attaining it.

Grecian Colonies.

We next come to the class of colonies which are exemplified in the case of those sent out by the Greeks; and we take them in order posterior to the Roman, because there is something in them for which rather more of explanation is required. Of those early migrations, which carried a Greek population into Asia Minor, and at a later period into Italy and Sicily, we have not a sufficient number of historical facts, to know very accurately the cause. And it may be, that internal commotions, as often as a superabounding population, were the source from which they were derived. When, of two contending parties, one acquired the ascendancy, they frequently made the situation of their opponents so painful to them, and sometimes also the shame of defeat was so great, that the vanquished party chose rather to live anywhere, than subject to the power and contempt of those over whom they had hoped to dominate. The leaders proposed emigration, and a great part of those who contended under their banners were ready to depart along with them. In this way they might remove in large bodies, and, carrying with them all their moveable effects, would be in circum-

Colony.

stances, when they established themselves on a fertile soil, to attain, in a little time, a great degree of prosperity. All this seems necessary to account for so great a degree of prosperity as was attained very early by the Greeks in Asia Minor, where arts and sciences flourished sooner, and civilization made still more rapid strides, till checked by Persian domination, than in the mother country itself, where a more dense population, and a less fertile soil, opposed obstructions to the happiness of the people, and the progress of the human mind.

There is nothing in modern times which so much resembles the colonization of Asia Minor by the Greeks, as the colonization of North America by the English. Of the first English planters of North America, a large proportion went out to escape the oppression of a predominating religion, as the Greeks to escape the oppression of a predominating political party. One difference there was, in that the English did not go off, at once, in any considerable bodies, under distinguished leaders, or with any great accompaniment of capital, the means of future prosperity. Accordingly, the prosperity of the British colonies in North America was much less rapid, and much less brilliant, than that of the Grecian colonies in Asia Minor. Another great difference there was, in that the English colonies, though they made a sort of subordinate government for themselves, were still held to be subject to the government of the mother country. The Grecian colonies became states, in all respects independent, owning no government but that which they established for themselves; though they still looked to the mother country for protection and assistance, and held themselves under a very strong obligation to befriend and assist her in all her difficulties.

In regard to those detachments of the population of the Grecian states which made themselves, either from political disgust, or political oppression, there is nothing which stands in need of explanation. The motive which gave rise to them is familiar and obvious; and the sort of relation in which they and the mother country stood to one another, importing mutual benevolence, but no right in the one to command, or obligation on the other to obey, every body can immediately understand.

There were other occasions, however, on which the Greeks sent out colonies, and these are the colonies which are commonly meant, when the Grecian principle of colonization is spoken of by way of distinction. These colonies were sent out, when the population of the mother country became superabundant, and relief was demanded by a diminution of numbers. This is a ground of colonization, which, since the principle of population has been shown to exert so great an influence upon the condition of human beings, deserves profound regard. We shall not therefore pass it by, without a few observations.

A population is said to be redundant—When? Not when it is numerically of either great or small amount; but solely and exclusively when it is too great for the quantity of food. Any one country produces or procures a certain quantity of food in the year. If it has a population greater than such

Colony.

Colony.

Effects of
the Principle
of Popula-
tion in
Greece

a quantity of food is sufficient to maintain, all that number which is over and above what it is capable of maintaining is a redundancy of population.

A curious phenomenon here presents itself. A redundancy of population, in the states of ancient Greece, made itself visible even to vulgar eyes. A redundancy of population in modern Europe never makes itself visible to any but the most enlightened eyes. Ask an ordinary man, ask almost any man, if the population of his country is too great,—if the population of any country in Europe is, or ever was too great?—so far, he will tell you, is it from being too great, that good policy would consist in making it, if possible, still greater; and he might quote, in his own support, the authority of almost all governments, which are commonly at pains to prevent the emigration of their people, and to give encouragement to marriage.

The explanation of the phenomena is easy, but it is also of the highest importance. When the supply of food is too small for the population, the deficiency operates, in modern Europe, in a manner different from that in which it operated in ancient Greece. In modern Europe, the greatest portion of the food is bought by the great body of the people. What the great body of the people have to give for it is nothing but labour. When the quantity of food is not sufficient for all, and some are in danger of not getting any, each man is induced, in order to secure a portion to himself, to give better terms for it than any other man, that is more labour. In other words, that part of the population who have nothing to give for food but labour, take less wages. This is the primary effect, clear, immediate, certain. It is only requisite, farther, to trace the secondary, or derivative effects.

When we say, that, in the case in which the supply of food has become too small for the population, the great body of the people take less wages, that is, less food for their labour, we mean that they take less than is necessary for comfortable subsistence; because they would only have what is necessary for comfortable subsistence in the case in which the supply of food is not too small for the whole.

The effect then of a disproportion between the food and the population, is not to feed to the full measure that portion of the population which it is sufficient to feed, and to leave the redundant portion destitute; it is to take, according to a certain rate, a portion of his due quantity from each individual of that great class who have nothing to give for it but ordinary labour.

What this state of things imports, is most easily seen. That great class, who have nothing to give for food but ordinary labour, is the great body of the people. When every individual in the great body of the people has less than the due quantity of food, less than would fall to his share if the quantity of food were not too small for the population, the state of the great body of the people is the state of sordid, painful, and degrading poverty. They are wretchedly fed, wretchedly clothed, have wretched houses, and neither time nor means to keep either their houses or their persons free from disgusting impurity. Those of them, who, either from bodily in-

firmities, have less than the ordinary quantity of labour to bestow, or from the state of their families need a greater than the ordinary quantity of food, are condemned to starve; either wholly, if they have not enough to keep them alive, or partially, if they have enough to yield them a lingering, diseased, and after all a shortened existence.

What the ignorant and vulgar spectator sees in all this, is not a redundant population, it is only a poor population. He sees nobody without food who has enough to give for it. To his eye, therefore, it is not food which is wanting, but that which is to be given for it. When events succeed in this train, and are viewed with these eyes, there never can appear to be a redundancy of population.

Events succeeded in a different train in the states of ancient Greece, and rendered a redundancy of population somewhat more visible even to vulgar and ignorant eyes.

In ancient Greece the greatest portion of the food was bought by the great body of the people; the state of whom, wretched or comfortable, legislation has never yet been wise enough much to regard. All manual labour, or at least the far greatest portion of it, was performed, not by free labourers serving for wages, but by slaves, who were the property of the great men. The deficiency of food, therefore, was not distributed in the shape of general poverty and wretchedness over the great body of the population, by reduction of wages; a case which affects, with very slight sensations, those who regard themselves as in no degree liable to fall into that miserable situation. It was felt, first of all, by the great men, in the greater cost of maintaining their slaves. And what is felt as disagreeable by the great men is sure never to continue long without an effort, either wise or foolish, for the removal of it. This law of human nature was not less faithfully observed in the states of ancient Greece for their being called republics. Called republics, they were, in reality, aristocracies; and aristocracies of a very bad description. They were aristocracies in which the people were cheated, with an idea of power, merely because they were able, at certain distant intervals, when violently excited, to overpower the aristocracy, in some one particular point; but they were aristocracies in which there was not one efficient security to prevent the interests of the many from being sacrificed to the interests of the few; they were aristocracies, accordingly, in which the interests of the many were habitually sacrificed to the interests of the few; meaning by the many, not the slaves merely, but the great body of the free citizens. This was the case in all the states of Greece, and not least in Athens. This is not seen in reading the French and English histories of Greece. It is not seen in reading Mitford, who has written a *History of Greece* for no other purpose, but that of showing that the interests of the many always ought to be sacrificed to the interests of the few; and of abasing the people of Greece, because every now and then, the many in those countries showed, that they were by no means patient under the habitual sacrifice of their interests to the interests of the few. But it is very distinctly seen among other places, in reading the Greek ora-

Colony.

tors, in reading Demosthenes for example, in reading the *Oration* against Midias, the *Oration* on Leptines, and others, in which the licence of the rich and powerful, and their power of oppressing the body of the people, is shown to have been excessive, and to have been exercised with a shameless atrocity, of which the gentleness and modesty of the manners of modern Europe, even in the most aristocratically despotic countries, do not admit.

In Greece, then, anything which so intimately affected the great men, as a growing cost of maintaining their slaves, would not long remain without serious attempts to find a remedy.

It was not, however, in this way alone, that a redundant population showed itself in Greece. As not many of the few citizens maintained themselves by manual labour, there were but two resources more, the land, and profits of stock. Those who lived on the profits of stock, commonly did so by employing slaves in some of the known arts and manufactures; and of course were affected by the growing cost of maintaining their slaves. Those who lived on the produce of a certain portion of the land could not fail to exhibit very distinctly the redundancy of their numbers, when by the multiplication of families, portions came to be so far subdivided, that what belonged to each was insufficient for his maintenance.

In this manner, then, it is very distinctly seen, why to vulgar eyes there never appears in modern Europe to be any redundancy of population, any demand for relieving the country by carrying away a portion of the people; and why, in ancient Greece, that redundancy made itself be very sensibly perceived; and created, at various times, a perfectly efficient demand for removing to distant places a great proportion of the people.

But what if that redundancy of population which shows itself in modern Europe, in the effects of reduced wages, and a poor and starving people, should suggest to rulers the policy of ancient Greece, and some time or other recommend colonization? A few reflections may be well bestowed upon a supposition of this kind.

General Remarks on the Principle of Population.

In the first place, it should be very distinctly understood what it is we mean, when we say, in regard to such a country as Great Britain, for example, that the supply of food is too small for the population. Because it may be said immediately, that the quantity of food may be increased in Great Britain; a proposition which no man will think of denying.

On this proposition, let us suppose that in any given year, this year for example, the food in Great Britain is too small for the people, by 10,000 individuals. It is no doubt true, that additional food sufficient to supply 10,000 individuals, might be raised next year; but where would be the amelioration, if 10,000 individuals were at the same time added to the numbers to be fed? Now, the tendency of population is such as to make, in almost all cases, the real state of the facts correspond with this supposition. Population not only rises to the level of the present supply of food; but, if you go on every year increasing the quantity of food, po-

Colony.

pulation goes on increasing at the same time, and so fast, that the food is commonly still too small for the people. This is the grand proposition of Mr Malthus's book; it is not only quite original, but it is that point of the subject from which all the more important consequences flow,—consequences which, till that point was made known, could not be understood.

When we say that the quantity of food in any country is too small for the quantity of the people, and that, though we may increase the quantity of food, the population will at the same time increase so fast, that the food will still be too small for the people; we may be encountered with another proposition. It may be said, that we may increase food still faster than it is possible to increase population. And there are situations in which we must allow that the proposition is true.

In countries newly inhabited, or in which there is a small number of people, there is commonly a quantity of land yielding a large produce for a given portion of labour. So long as the land continues to yield in this liberal manner, how fast so ever population increases, food may increase with equal rapidity, and plenty remain. When population, however, has increased to a certain extent, all the best land is occupied; if it increases any farther, land of a worse quality must be taken in hand; when land of the next best quality is all exhausted, land of a still inferior quality must be employed, till at last you come to that which is exceedingly barren. In this progression, it is very evident that it is always gradually becoming more and more difficult to make food increase with any given degree of rapidity, and that you must come at last to a point where it is altogether impossible.

It may, however, be said, and has been said in substance, though not very clearly, by some of Mr Malthus's opponents, that it is improper to speak of food as too small for the population, so long as food can be made to increase at an equal pace with population; and though it is no doubt true, that, in the states of modern Europe, food does not actually increase so fast as the population endeavours to increase, and hence the poverty and wretchedness of that population; yet it would be very possible to make food increase as fast as the tendency in population, and hence to make the people happy without diminishing their numbers by colonization; and that it is owing wholly to unfavourable, to ill-contrived institutions, that such is not the effect universally experienced.

As this observation has in it a remarkable combination of truth and error, it is worthy of a little pains to make the separation.

There can be no doubt that, by employing next year a greater proportion of the people upon the land than this year, we should raise a greater quantity of food; by employing a still greater proportion the year following, we should produce a still greater quantity of food; and, in this way, it would be possible to go on for some time, increasing food as fast as it would be possible for the population to increase. But observe at what cost this would be. As the land, in this course, yields gradually less and

Colony. less, to every new portion of labour bestowed upon it, it would be necessary to employ gradually not only a greater and greater *number*, but a greater and greater *proportion* of the people in raising food. But the greater the proportion of the people which is employed in raising food, the smaller is the proportion which can be employed in producing anything else. You can only, therefore, increase the quantity of food to meet the demand of an increasing population, by diminishing the supply of those other things which minister to human desires.

There can be no doubt, that, by increasing every year the proportion of the population which you employ in raising food, and diminishing every year the proportion employed in every thing else, you may go on increasing food as fast as population increases, till the labour of a man, added upon the land, is just sufficient to add as much to the produce, as will maintain himself and raise a family. Suppose, where the principle of population is free from all restriction, the average number of children reared in a family is five; in that case, so long as the man's labour, added to the labour already employed upon the land, can produce food sufficient for himself and the rearing of five children, food may be made to keep pace with population. But if things were made to go on in such an order, till they arrived at that pass, men would have food, but they would have nothing else. They would have neither clothes, nor houses, nor furniture. There would be nothing for elegance, nothing for ease, nothing for pleasure. There would be no class exempt from the necessity of perpetual labour, by whom knowledge might be cultivated, and discoveries useful to mankind might be made. There would be no physicians, no legislators. The human race would become a mere multitude of animals of a very low description, having just two functions, that of raising, and that of consuming food.

To shorten this analysis, let us, then, assume, what will hardly be disputed, that it is by no means desirable for human nature to be brought into a situation in which it would be necessary for every human being to be employed, and fully employed, in the raising of food; that it never can be desirable that more than a certain portion should be employed in the raising of food; that it must for ever be desirable that a certain proportion should be employed in producing other things which minister to human desires, and that there should be a class possessed of leisure, among whom the desire of knowledge may be fostered, and those individuals reared who are qualified to advance the boundaries of knowledge, and add to the powers and enjoyments of man.

It is no use, then, to tell us that we have the physical power of increasing food as fast as population. As soon as we have arrived at that point at which the due distribution of the population is made between those who raise food, and those who are in other ways employed in contributing to the well-being of the members of the community, any increase of the food, faster than is consistent with that distribution, can only be made at the expence of those other things, by the enjoyment of which the life of man is preferable to that of the brutes. At this point the progress of population ought undoubtedly

to be restrained. Population may still increase, because the quantity of food may still be capable of being increased, though not beyond a certain slowness of rate, without requiring, to the production of it, a greater than the due proportion of the population.

Suppose, then, when the due proportion of the population is allotted to the raising of food, and the due proportion to other desirable occupations, that the institutions of society were such as to prevent a greater proportion from being withdrawn from those occupations to the raising of food. This it would, surely, be very desirable that they should effect. What, now, would be the consequence, should population, in that case, go on at its full rate of increase,—in other words, faster than with that distribution of the population, it would be possible for food to be increased? The answer is abundantly plain: All those effects would take place which have already been described as following upon the existence of a redundant population, in modern Europe, and in all countries in which the great body of those who have nothing to give for food but labour, are free labourers:—that is to say, wages would fall; poverty would overspread the population; and all those horrid phenomena would exhibit themselves, which are the never failing attendants on a poor population.

It is of no great importance, though the institutions of society may be such, as to make the proportion of the population, kept back from the providing of food, rather greater than it might be. All that happens is, that the redundancy of population begins a little earlier. The unrestrained progress of population would soon have added the deficient number to the proportion employed in the raising of food; and, at whatever point the redundancy begins, the effects are always the same.

What are the best means of checking the progress of population, when it cannot go on unrestrained, without producing one or other of two most undesirable effects,—either drawing an undue proportion of the population to the mere raising of food, or producing poverty and wretchedness, it is not now the place to inquire. It is, indeed, the most important practical problem to which the wisdom of the politician and moralist can be applied. It has, till this time, been miserably evaded by all those who have meddled with the subject, as well as by all those who were called upon by their situation to find a remedy for the evils to which it relates. And yet, if the superstitions of the nursery were discarded, and the principle of utility kept steadily in view, a solution might not be very difficult to be found; and the means of drying up one of the most copious sources of human evil; a source which, if all other sources of evil were taken away, would alone suffice to retain the great mass of human beings in misery, might be seen to be neither doubtful nor difficult to be applied.

The only question for which we are here required to find an answer, is that of colonization. When the population of a country is full, and its increase cannot go on, at its most rapid pace, without producing one of the two evils of redundancy, a portion of the people, sent off to another country, may create a

Colony.

Connection
of this Prin-
ciple with
Coloniza-
tion.

Colony.

void, which, till population fills up, it may go on as rapidly as before, and so on for any number of times.

In certain circumstances, this is a more desirable resource, than any scheme for diminishing the rate of population. So long as the earth is not peopled to that state of fulness which is most conducive to human happiness, it contributes to that important effect. It is highly desirable, on many accounts, that every portion of the earth, the physical circumstances of which are not inconsistent with human well-being, should be inhabited, as fully as the conditions of human happiness admit. It is only, in certain circumstances, however, that a body of people can be advantageously removed from one country, for the purpose of colonizing another. In the first place, it is necessary, that the land which they are about to occupy should be capable of yielding a greater return to their labour than the land which they leave; otherwise, though relief is given to the population they leave behind, their own circumstances are not better than they would have been had they remained.

Another condition is, that the expence of removal from the mother country to the colonized country, should not be too great; and that expence is usually created by distance.

If the expence is too great, the population which remains behind in the mother country, may suffer more by the loss of capital, than it gains by the diminution of numbers.

It has been often enough, and clearly enough, explained, that it is only capital which gives employment to labour; we may, therefore, take it as a postulate. A certain quantity of capital, then, is necessary, to give employment to the population which any removal for the sake of colonization may leave behind. But if, to afford the expence of that removal, so much is taken from the capital of the country, that the remainder is not sufficient for the employment of the remaining population, there is, in that case, a redundancy of population, and all the evils which it brings. For the well-being of the remaining population, a certain quantity of food is required, and a certain quantity of all those other things which minister to human happiness. But to raise this quantity of food, and this quantity of other things, a certain quantity of capital is indispensably necessary. If that quantity of capital is wanting, the food, and other things, cannot be obtained.

Of that class of colonies, in the conception of which the idea of the people is the predominating idea, we have now explained the principle which is exemplified in the case of the Roman, and that which is exemplified in the case of the Grecian colonies. Belonging to the same class, there are British colonies, in which another, and a very remarkable principle is exemplified. The Greeks planted colonies for the sake of getting rid of a redundant population,—the British, for the sake of getting rid of a delinquent population.

The bright idea of a colony for the sake of getting rid of a delinquent population, if not peculiar to English policy, is, at any rate, a much more remarkable part of the policy of England, than of that of any other country. We have not time here to trace

the history of this very singular part of English policy, nor is it of much importance. Every body knows, that this mode of disposing of delinquents was carried to a considerable height, before this country lost her dominion over the North American colonies, to which she annually transported a considerable portion of her convicts. It will suffice for the present occasion, to offer a few observations on the nature of such an establishment as that of New South Wales.

Considered in the light of its utility as a territory, the colony of New South Wales will be included in the investigation of that class of colonies, in the conception of which the idea of territory is the predominating idea. At present it is to be considered in its capacity of a place for receiving the delinquent part of the British population.

In dealing with a delinquent population, the end to be aimed at,—the security of the non-delinquent,—is considered as double; security from the crimes of this or that individual delinquent himself, and security from those of other men who may be tempted to follow his example. The first object is comparatively easy. It is not difficult to prevent an individual from doing any mischief. What is chiefly desirable is, that the individual who is proved to be a delinquent, should be so dealt with, that the mode of dealing with him may be as effectual as possible in deterring others from the commission of similar offences.

In regard to the first object,—securing society from the crimes of the convicted individual,—there is a good mode, and a bad mode. The best of all modes, unquestionably, is, the reformation of the offender. Wherever this can be accomplished, every other mode, it is evident, is a bad mode. Now, in regard to the reformation of the offender, there is but one testimony,—that New South Wales, of all places on the face of the earth, except, perhaps, a British prison, is the place where there is the least chance for the reformation of an offender,—the greatest chance of his being improved and perfected in every species of wickedness.

If it be said, that taking a man to New South Wales, at any rate affords to the British community security against the crimes of that man; we may answer, that putting him to death would do so too. And we farther pronounce, that saving a man from death with the mind of a delinquent, and sending him to New South Wales to all the effects of his vicious propensities, is seldom doing even him any good.

It is, however, not true, that sending a delinquent to New South Wales secures the British community from his future offences. A very great proportion of those who are sent to New South Wales find the means of returning; and those who do so are, in general, and may always be expected to be, the very worst.

We have a high authority for this affirmation. The committee of the House of Commons, who were appointed in the session of 1812 “to inquire into the manner in which sentences of transportation are executed, and the effects which have been produced by that mode of punishment,” stated so-

Colony.

Colony.

lemnly in their *Report*, that "No difficulty appears to exist among the major part of the men who do not wish to remain in the colony, of finding means to return to this country. All but the aged and infirm easily find employment on board the ships visiting New South Wales, and are allowed to work their passage home. But such facility is not afforded to the women. They have no possible method of leaving the colony but by prostituting themselves on board the ships whose masters may choose to receive them. They who are sent to New South Wales, that their former habits may be relinquished, cannot obtain a return to this country, but by relapsing into that mode of life which, with many, has been the first cause of all their crimes and misfortunes. To those who shrink from these means, or are unable, even thus, to obtain a passage for themselves, transportation for seven years is converted into a banishment for life, and the just and humane provisions of the law, by which different periods of transportation are apportioned to different degrees of crime, are rendered entirely null."

So much then with regard to the reformation of the individual, and security from his crimes, neither of which is attained. But, even on the supposition that both were ever so completely attained, there would still be a question of great importance; viz. whether the same effects could not be attained at a smaller expence. It never ought to be forgotten, that society is injured by every particle of unnecessary expence; that one of the most remarkable of all the points of bad government is, that of rendering the services of government at a greater than the smallest possible expence; and that one of the most remarkable of all the points of good government is, that of rendering every service which it is called upon to render at the smallest possible expence.

In this respect also, the policy of the New South Wales establishment is faulty beyond all endurance. The cost of disposing in this way of a delinquent population is prodigious. We have no room for details, and there is no occasion for proof: the fact is notorious. Whereas, it is now well known, that, in houses of industry and reformation upon the best possible plan, that, for example, of Mr Bentham's *Panopticon*, which has no parallel, there is little or no expence, there is perfect security against the future crimes of the delinquent, and that to a great degree, by the best of all possible modes,—his reformation.

Thus wretched is the mode of dealing with a delinquent according to such an institution as that of New South Wales, as far as regards the securing of the community from the future crimes of the convicted delinquent. It remains, that we consider it in what regards the deterring of all other men from following similar courses to those of the delinquent.

It is very evident, that this last is by far the most important of the two objects. It is now agreed that this is the end, the only good end, of all punishment, properly so called; for mere safe custody, against the chance of future crimes, and satisfaction to the injured party, are not, in the proper sense of the word, punishments; they are for other ends than

punishment, in any point of view in which it is ever contemplated. Colony.

The great importance of this above the previous case, consists in this, that when you take security against the crimes of the convicted delinquent, you take security against the crimes of only one man, and that a man in your hands, with whom you can deal as you please. When, by means of the mode of dealing with him, you deter all other men from following similar courses, you provide security, not against one man alone, but many men, any number of men, of men undetected, and not in your power, each of whom may be guilty of many crimes before he can be stopt.

On this point it is only necessary, for form's sake, to write down what is the fact; for every human being of common reflection, must anticipate the observation before it is made. If an assembly of ingenious men, in the character of legislators, had sitten down to devise a method of dealing with delinquents, which, while it had some appearance of securing society from the crimes of the detected individual, should be, to the greatest possible degree, devoid, both of the reality and even the appearance of any efficacy, by its example, of deterring other men from the pursuit of similar courses, they could not have devised any thing better calculated for that preposterous end than the colony of New South Wales. Nothing can operate where it does not exist. The men to be operated upon are in England; the example which should operate is in New South Wales. Much more might be said, but it is unnecessary. In the great majority of cases, a voyage to New South Wales, has not even the appearance of a punishment. Men of that description have neither friends nor affections. They leave nobody or thing whom they like, and nobody who likes them. What is it to such men that they are for a while, or for ever, taken away from England, along, very frequently, with the only sort of persons with whom they have any connection, the companions of their debaucheries and of their crimes?

We now come to the second grand division of colonies, those, in the conception of which, the idea of territory is the predominating idea. Of this sort are most of the colonies of the states of modern Europe; the British possessions, for example, in the East and West Indies. Examination of the supposed Advantages of Colonies.

The question is, in what way, or ways, abstracting from the questions of population, an outlying territory, considered merely as territory, is calculated to be advantageous; or, in other words, what reasons can any country have for desiring to possess the government of such territories.

There are two ways, which will easily present themselves to every mind, as ways in which advantage may accrue to the governing country. First, these outlying dominions may yield a tribute to the mother country; secondly, they may yield an advantageous trade.

1. We shall consider the first supposition; that of their yielding a tribute to the mother country. This will not require many words, as it is a supposition which few will be found to entertain. In regard to the West Indies, no such idea as that of a tribute

Colony.

has ever been formed. Even in regard to those taxes, which a vain and unprofitable attempt was made to impose upon the formerly existing colonies in North America, they were never dreamt of as a tribute, and never spoken of but in a sense contrary to the very idea of a tribute, that of reimbursing to the mother country a part, and no more than a part, of that which they cost her in governing and defending them.

With regard to the East Indies, we believe, there exists more or less of prejudice. Under the ignorance in which the country has remained of East India affairs, it floats in the minds of a great many persons, that, some how or other, a tribute, or what is equivalent to a tribute, does come from the East Indies. Never did an opinion exist more completely, not merely without evidence, but contrary to evidence, evidence notorious, and well known to the persons themselves by whom the belief is entertained. India, instead of yielding a tribute to England, has never yielded enough for the expence of its own government. What is the proof? That its government has always been in debt; and has been under the necessity of continually augmenting its debt, till it has arrived at a magnitude which is frightful to contemplate.

So far is India from yielding a tribute to Great Britain, that, in loans and aids, and the expence of fleets and armies, it has cost this country enormous sums. It is no doubt true, that some acts of Parliament have assumed the existence of a tribute from India, or what has been called a surplus revenue, for the use of the nation. But Parliament, we have pretty good experience, cannot make things just by affirming them. *Things* are a little more stubborn than the credulity of Englishmen. That is, in general, obedient enough to the affirmation of those who lead the Parliament, and who have sometimes an interest in leading it wrong. *Facts* take their own course, without regard to the affirmations of Parliament, or the plastic faith of those who follow them.

A general proposition, on this subject, may be safely advanced. We may affirm it, as a deduction from the experienced laws of human society, that there is, if not an absolute, at least, a moral impossibility, that a colony should ever benefit the mother country, by yielding it a permanent tribute.

Let any body but consider what is included in the word government. And, when he has done that, let him then tell himself that the colonies must be governed. If he has the sufficient quantity of knowledge and reflection, no further proof will be necessary.

No proposition in regard to government is more universal, more free from all exception than this, that a government always spends as much as it finds it possible or safe to extract from the people. It would not suit the limits of the present design to run over the different governments of the world for the experimental proof of this proposition. We must invite every reader to do it for himself. Of the thing we are perfectly sure, that the more profoundly he is read in history, the more thoroughly will he be convinced of the universality of the fact.

Now, then, consider whether this universal fact be

not inconsistent with the idea of benefit to the mother country by receiving a tribute from the colony. The government of the mother country itself cannot keep its expences within bounds. It takes from the people all it can possibly take, and is still going beyond its resources. But if such is the course of government at home, things must be worse in the colonies. The farther servants are removed from the eye of the master, the worse, generally speaking, their conduct will be. The government of the colonies, managed by delegates from home, is sure to be worse, in all respects, than the government at home; and, as expence is one of the shapes in which the badness of government is most prone to manifest itself, it is sure, above all things, to be in proportion to its resources more expensive. Whatever springs operate at home to restrain the badness of government, cannot fail to operate with diminished force at the distance of a colony. The conclusion is irresistible. If the government of the mother country is sure to spend up to the resources of the country; and a still stronger necessity operates upon the government of the colony to produce this effect, how can it possibly afford any tribute?

If it be objected to this conclusion, that this propensity of governments to spend may be corrected, we answer, that this is not the present question. Take governments as, with hardly any exception, they have always been (this is a pretty wide experience); and the effect is certain. There is one way, to be sure, of preventing the great evil, and preventing it thoroughly. But there is only one. In the constitution of the government, make the interest of the many to have the ascendancy over the interest of the few, and the expence of government will not be large. The services expected from government may, generally speaking, be all rendered in the best possible manner at very little expence. Whenever the interests of the many are made, in the framing of governments, to have the ascendancy over the interests of the few, the services of government will always be rendered at the smallest possible expence. So long as the interests of the few are made in governments to have the ascendancy over the interests of the many, the services of government are all sure to be rendered, at the greatest possible expence. In almost all governments that ever yet existed, the interest of the few has had an ascendancy over the interest of the many. In all, the expence of government has, accordingly, been always as great, as, in existing circumstances, the people could be made, or could be made with safety, to give the means of making it.

One other supposition may be urged in favour of the tribute. The expence, it may be said, of governing the colony by a deputation from the mother country, may be escaped, by allowing the colony to govern itself. In that case, the colony will not choose to pay a tribute. If the tribute rests upon the ground of friendship, it will not be lasting. If the mother country extorts it by force, the colony is, in fact, governed by the mother country; and all the expence of that mode of government is ensured. If it be urged that the colony may continue to pay a

Colony.

Colony. tribute to the mother country, and that voluntarily, because the mother country may be of use to it; that, we may answer, is a bargain, not a tribute. The mother country, for example, may yield a certain portion of defence. But the colony is saved from the expence of providing for itself that defence which it receives from the mother country, and makes a good bargain if it gets it from the mother country cheaper than it would be provided by itself. In this case, too, the expence incurred by the mother country is apt to be a very full equivalent for the tribute received. It is evident, that this sort of bargain may subsist between any two states whose circumstances it may suit, and is not confined to a mother and daughter country. It is therefore no part of the question relating to colonies.

Inquiry as to the Advantages to be got by Trade.

2. We have now investigated the first of the modes in which a colony, considered as territory merely, may be expected to benefit the mother country; and we have seen the chances of good which it affords. We shall now proceed to investigate the second; the trade, by means of which it is supposed that colonies may benefit the mother country.

This is a topic of some importance; for it is on account of the trade that colonies have remained an object of affection to Englishmen. It is on account of trade solely that the colonies in the West Indies are valued. It is indeed true, that some idea of something like a tribute from the East Indies has till this time maintained a place in the minds of the unthinking part of the community. But still it is the trade which has been supposed to be the principal source of the advantage which has been ascribed to what we call "the British Empire in the East."

Dr Adam Smith produces a long train of reasoning to prove, that it never can be advantageous to a country to maintain colonies merely for the sake of their trade.

View of Dr Smith's Reasonings.

In the idea of deriving a peculiar advantage from the trade of the colonies, is necessarily included the idea of monopoly. If the trade of the colony were to be free, other nations would derive as much advantage from it as the mother country; and the mother country would derive as much advantage from it, if the colony were not a colony.

Dr Smith affirms that this monopoly can never be of any advantage; must always, on the contrary, be a source of great disadvantage to the mother country.

He argues thus:—To make the monopoly advantageous to the mother country, it must enable the mother country to buy cheaper, or sell dearer, in the colony, than it would otherwise have done. In other words, it must enable the mother country to obtain the goods of the colony for a smaller quantity of her own goods than she could without the monopoly. This, in the opinion of Dr Smith, it does not belong to the monopoly to accomplish. The monopoly, he says, may enable the mother country to make other nations pay dearer for the goods of the colony, but it cannot enable her to buy them cheaper. This he seems to take as a postulate, without attempting much to support it by reasoning. The extension of the market, he says, by which he must mean, the

competition of capital, would, in a state of freedom, reduce the profits of stock in the colonies to their lowest terms. Under a monopoly he seems to think that profit of stock in the colonies is apt to remain above that level. And he assumes, that the terms on which the mother country deals with the colony must depend upon the rate of profits in the colony.

Having, on these grounds, assumed the impossibility of deriving any advantage from the monopoly of the colonial trade, Dr Smith proceeds to represent a variety of disadvantages which he thinks it has a necessary tendency to produce.

His argument is, that the monopoly of the colonial trade necessarily raises the profits of stock in the mother country; and that "whatever," to use his own expression, "raises in any country the ordinary rate of profit higher than it otherwise would be, necessarily subjects that country both to an absolute and to a relative disadvantage, in every branch of trade of which she has not the monopoly."

To prove the first of these propositions, he says, that by the monopoly of the trade of any colony, foreign capital is driven from it; the capital of the trade is thus made deficient; the profit of the capital is, for that reason, increased; the increase of profit in the colony draws capital from the mother country; the departure of capital from the mother country makes the portion of capital in the mother country deficient; and hence raises in the mother country the profits of stock.

To prove the second of the propositions, he says, that high profits produce high prices; and that high prices diminish produce. To afford her merchants the high profits in question, the country must pay dearer for the goods she imports; and must sell dearer those which she exports. She must therefore, he infers, "both buy less and sell less; must both enjoy less and produce less, than she otherwise would do." Nor is this all; other nations, who do not subject themselves to this disadvantage, to this diminution of produce, may advance faster, and thus attain a superiority which they would not otherwise have enjoyed. And there is still a worse evil; "by raising the price of her produce above what it would otherwise be, it enables the merchants of other countries to undersell her in foreign markets, and thereby to jostle her out of almost all those branches of trade of which she has not the monopoly."

To this reasoning, Dr Smith anticipates an objection. It may be affirmed, that the colony trade is more advantageous than any other trade; and though it may be true, according to the reasonings of Smith, that the monopoly of the colony trade has diminished the amount of trade which the mother country,—which England, for example, has been able to carry on in other channels; England has lost nothing, because she has exchanged a less profitable for a more profitable employment of her capital.

In answer to this objection, Dr Smith endeavours to prove, that the employment into which the capital of England is forced by the monopoly, is less advantageous to the country than that into which it would have gone of its own accord. As the foundation of his reasoning, he assumes, that "the most

Colony.

advantageous employment of any capital to the country to which it belongs, is that which maintains there the greatest quantity of productive labour, and increases the most the annual produce of the land and labour of that country." Upon this principle, he maintains, that the home trade is more advantageous than any trade of export and import, because the same capital puts in motion two portions of industry, that of the buyer and that of the seller. That the trade of export and import, in which the returns of capital take place at short intervals, is more advantageous than a trade in which they take place at distant intervals; as a capital which returns, for example, twice in the year, puts in motion twice as much industry in the mother country, as one which returns only once in the year: And that a carrying trade is the least advantageous of all trades, because it serves to put in motion, not the industry of the country to which it belongs, but the industry of the two countries, the communication between which it is employed to maintain. The colony is, therefore, less advantageous than the home trade; it is less advantageous than the trade with the neighbouring countries of Europe; and a great proportion of it is less advantageous than any trade of export and import, because it is a mere carrying trade. The employment into which the capital of Great Britain is forced by the monopoly of the colony trade, is, therefore, a less advantageous employment than that into which it would have gone of its own accord.

We have stated this train of reasoning, which hitherto has passed with political economists as conclusive, the more carefully, because there are several positions in it, which the late profound work of Mr Ricardo (*Principles of Political Economy and Taxation*), who has thrown so much light upon the science of Political Economy, has taught us to control.

Remarks on
Dr Smith's
Reasonings.

First, as to the position, that the monopoly of the trade of a colony cannot enable the mother country to buy cheaper or sell dearer in the colony; in other words, to obtain a given quantity of the goods of the colony for a less quantity of her own goods, than she would otherwise do, Mr Ricardo would reason as follows: If the trade of the colony is left open to all the merchants of the mother country, it will no doubt happen, that the competition of these merchants, one with another, will make them sell as cheap in the colony as they can afford to sell, that is, buy as dear as they can afford to buy. The produce of the colony will, in that case, go as cheap to the foreign as to the home consumer.

But there is another case; namely, that in which the trade of the colony is placed in the hands of an exclusive company. In that case it is, on the other hand, true, that the mother country may obtain a given quantity of the goods of the colony for a less quantity of her own goods than otherwise she would do. In this case, the goods of the mother country are placed, with regard to the goods of the colony, in the situation in which those commodities which can only be produced in a limited quantity, particular wines, for example, which can only be produced on one particular spot, are placed with regard to all the

Colony.

rest of the goods in the world. It is evident that any quantity of the rest of the goods in the world may be given for those wines, if people are sufficiently desirous to possess them; that there is no limit, in short, to the quantity, but the unwillingness of people to part with more of the things which they possess to obtain the commodities which are thus in request. The same would be the case with a colony, the trade of which was entirely in the hands of an exclusive company. The exclusive company, by limiting the quantity of the goods of the mother country which they chose to send to the colony, might compel the colony to give for that limited quantity any quantity of the produce of their own land and labour, which their desire to obtain the goods of the mother country would admit. If the goods of the mother country were goods which excited a very strong desire, if they were goods of the first necessity, the necessary materials of food or the instruments of their industry, there would be no limit but one to the greatness of the quantity of their own produce which they might be compelled to pay for a given quantity of the produce of the mother country. When nothing was left to the colony of the whole produce of its labour but just enough to keep the labourers alive, it could not go any farther. Up to that point, if dependent for articles of the first necessity, it might, by an exclusive company, undoubtedly be stripped.

Even in the other case of the monopoly, that in which the trade with the colony is not placed in the hands of an exclusive company, but open to all the merchants of the mother country, one situation of the mother country may be supposed, in which she might still draw an extraordinary advantage from the forced trade of the colony.

The facts would be these. Whatever foreign goods the colony bought, she would be still obliged to purchase from the mother country. No doubt, the competition of the merchants of the mother country would, in this case, compel them to sell as cheap to the colony as to any other country. Wherein, then, would consist the advantage? In this, that England might thus sell in the colony, with the usual profits of stock, certain kinds of goods, which not being able to manufacture so cheaply as some other countries, she would cease to manufacture, except for the monopoly. But still a very natural question arises,—What advantage does she derive from forcing this manufacture, since she makes by it no more than the ordinary profits of stock, and might make the ordinary profits of stock by the same capital in some other employment? The answer is, that she might by this means obtain a greater quantity of the goods of the colony, by a given quantity of the produce of her own labour, or, what comes to the same thing, an equal quantity of the goods of the colony, by a less quantity of the produce of her own labour, than she could in a case of freedom.

It may be seen to be so in this manner. England desires to purchase, say 10,000 hogsheds of sugar. This is her consumption. For this she will give, of the produce of her own labour, whatever quantity it is necessary to give. She wishes, however, to give as little as possible; and the question is, in what way

Colonies. she may give the least. The sugar is worth, say L. 500,000. England sends goods to the colony which sell for L. 500,000. Now, apply the supposition introduced above. Suppose that, if trade were free, these goods from England, which the manufacturers and merchants of England cannot afford to sell for less than L. 500,000, could be had for L. 400,000 from some other country. In that case, it is evident that the same quantity of these same goods with which England, under the monopoly, purchased 10,000 hogsheds of sugar, would now purchase only 8000; for that is the ratio of the L. 400,000 to the L. 500,000. What then would happen, supposing England still to resolve upon having 10,000 hogsheds of sugar? One of two things must of necessity happen. Either she will purchase the sugar with the same goods, or she will not. If she purchases it with the same goods, it is evident that she must give a greater quantity of goods; she must give one fifth more of the produce of her labour; one fifth more of her industrious people must be withdrawn from administering to other productions, and employed in enabling her to obtain the same quantity of sugar. This quantity of produce, in that case, the mother country saves by means of the monopolized trade of the colony. This quantity she loses by losing such a colony. But, undoubtedly, the mother country would, in such a case, endeavour to purchase the sugar, not with such goods as she purchased it with before, but other goods. She would endeavour to purchase it with goods which she could manufacture as cheaply as any other country. But supposing the colony had no demand for any goods which the mother country could afford as cheap as any other country, even in that case the mother country would still have a resource. If there was any country in which she could sell such goods for money, she could purchase the same quantity of sugar for the same quantity of the produce of her own labour as before.

It is not then true, according to Dr Smith, that in no case can the mother country derive any peculiar advantage in the way of trade, from the possession of colonies. We see that there are two cases, in which she may derive an advantage in that way. It remains to inquire what that advantage is ultimately worth; not only what it is in itself independently, but what it is, after compensation is made for all the disadvantages with which the attainment of it is naturally attended.

We are first to inquire, What is the value of that advantage, all deductions made, which the mother country may derive, through an exclusive company, from the trade of a colony?

No ultimate Advantage derived from the exclusive Trade of Colonies. It is very evident, in the first place, that, whatever the mother country gains, the colony loses. Now, if the colony were part of the dominions of a foreign state, there is a certain way of viewing such questions, in which that result would appear to be perfectly desirable. But, suppose that the colony, which is the fact, is not part of the dominions of a foreign state, but of the same state; that it is, in truth, not part of a different country, but of the same country; its subjects, not part of a different community, but of the same community; its poverty or riches, not

the poverty or riches of another country, but of the same country; How is the result to be viewed in that case? Is it not exactly, the same sort of policy, as if Yorkshire were to be drained and oppressed for the benefit of Middlesex? What difference does it make, that one of the portions of the same empire is somewhat farther off than another? Would it, for that reason, be more rational to pillage Caithness, than to pillage Yorkshire, for the sake of Middlesex? Does the wealth of a state consist in the wealth of one part, effected by the poverty of another part? Does the happiness of a state consist in the happiness of one part, effected by the misery of another? What sort of a rule for guiding the policy of any state would this be supposed? Absurdly this would be a contrivance, not for increasing her wealth and happiness, upon the whole. It would be a contrivance for diminishing it. In the first place, when of two parties equally provided with the means of enjoyment, you take a portion from the one, to give it to the other, the fact is,—a fact too well established, and too consonant with the experience of every man, to need illustration here,—that you do not add to the happiness of the one, so much as you take from the happiness of the other; and that you diminish the sum of their happiness taken together. This, in truth, is the foundation, upon which the laws for the protection of property rest. As the happiness of one man is, or ought to be, of no more value to the state, than the happiness of another man, if the man who takes from another man a piece of property, added to his own happiness, as much as he took from the happiness of the other, there would be no loss of happiness upon the whole, and the state would have no ground, in utility, on which to interfere.

But this is not all. Not only is the quantity of happiness of the community diminished upon the whole, but by that operation which gives the mother country an advantage by the trade of the colony, the quantity of produce of the community is diminished upon the whole. The subjects of the state, taken as a whole, not only enjoy less than they would otherwise enjoy, but they produce less than they would otherwise produce. The state is not a richer state; it is, on the contrary, a poorer state, by means of such a colonial policy.

By means of such a policy, a portion of the capital of the state is employed in a channel in which it is less productive than it would have been in the channel into which it would have gone of its own accord. It is a point established in the science of Political Economy, that it is not good policy to confine consumption to any sort of home manufacture, when it can be purchased more cheaply abroad. It is upon this ground that we have laughed at the late and present outcries of the Germans, because the English sell their goods cheaper than they can make them. The reason is, because when a country continues to consume an article made at home, which it could get cheaper from another country, it does neither more nor less than insist, that it shall employ a certain number of men's labour in providing it with that article, more than it would be necessary to employ if it imported the article; and,

Colony.

of course, it loses completely the benefit of these men's labour, who would be employed in producing for it something else, if they were not employed in producing that article. The country is, therefore, the poorer, by the whole value of these men's labour. The case is exactly the same, where the colonies are confined to the manufactures of the mother country. When the colony is obliged to employ, for the purpose of obtaining a certain quantity of goods from the mother country, the labour of a greater number of men than she would be obliged to employ to get the same quantity of goods from another country, she loses the labours of all that additional number of men. At the same time, the mother country does not gain it; for, if the mother country did not manufacture for the colony, her capital would be liberated to another employment, and would yield the same profits in that as it did in the former employment.

We have still, however, to examine that extraordinary case which we before supposed, in which the mother country cannot produce any sort of commodity whatsoever as cheap as other countries; and, if trade were free, of course would sell nothing in a foreign market. The case here is somewhat altered. In liberating the colony from the monopoly of the mother country, there would be no change of capital from a less to a more productive employment; because, by the supposition, the mother country has not a more productive employment to which her liberated capital can be sent. Events would succeed in the following order: The colony would obtain the goods which it demanded, with a smaller portion of its own labour,—would hence be more amply supplied with goods. But it is not supposed that this event would give to its industry a more beneficial direction. In the case of a sugar colony, at any rate, its industry would remain in the same channels as before. Such would be the effects in regard to the colony. What would they be in regard to the mother country? If her capital is no longer employed in manufacturing for the colony, she can always, indeed, employ it with the same profit as before. But she still desires the same quantity of sugar; and her goods will not go so far as before in the purchase of it. Whatever fall would be necessary in the price of her goods to bring them upon a level with the goods of other countries, is equivalent, as far as she is concerned, to a rise of the same amount, in the price of sugar. In this case, the mother country would lose exactly as much as the colony would gain. The community, taken as a whole, would be neither the richer nor the poorer, for driving things out of the free into the compulsory channel. The people of the mother country would be so much the richer,—the people of the colony would be so much the poorer.

This, however, still remains to be said. There is only one case in which this sort of monopoly would not diminish the produce of the community, and render it positively poorer upon the whole. There is only that one case, supposed above, in which the mother country has not one commodity which she can sell as cheap as other countries. Now this may fairly be regarded as a case, if not altogether, at any

rate very nearly impossible. It is not easy to conceive a country so situated, as not to have advantages in regard to the production of some sorts of commodities, which set her on a level with other countries. As long as this is the case, she can obtain money on as good terms as any other country; and if she can obtain money on as good terms, she can obtain sugar, and every thing else.

The question, then, as to the benefit capable of being derived from a colony through the medium of an exclusive trade, is now brought to a short issue. There is no benefit, except through the medium of a monopoly. There is only one case in which the monopoly does not make the whole community poorer than it would otherwise be. In that case, it does not make the community richer than it would otherwise be; and that case is one, which can either never be realized, or so rarely, as to be one of the rarest of all exceptions to one of the most constant of all general rules. The policy of holding a colony for the benefit of its trade, is, therefore, a bad policy.

To these conclusions, one or two of the doctrines of Dr Smith will be seen to be opposed, and, therefore, require a few words of elucidation. Farther Remarks on Dr. Smith.

If an advantage, in the two cases just explained, would arise from colonies, it would be counterbalanced, he says, by the disadvantage attending the rise in the profits of stock.

Both parts of this doctrine may be disputed. In the first place, it may be disputed, whether the monopoly of the colony trade has any tendency to raise the profits of stock in the mother country. In the next place, it may be disputed, whether a high rate of profits in any country, has any tendency to lay it under any disadvantage in its traffic with other nations.

First, it may be disputed, whether the monopoly of the colony trade would increase profits. The expulsion of foreign capital would create a vacuum, whence, according to Smith, a rise of profit, and an absorption of capital from the mother country. The question is, whether capital would not flow into the colonies from the mother country, till it reduced the profits in the colony, to the level of the profits in the mother country, instead of raising those in the mother country, in any degree toward a level with those of the colony. That it would do so appears to be capable of demonstration. Mr Ricardo's argument would be very short. Nothing, he would say, can raise the profits of stock, but that which lowers the wages of labour. Nothing can lower the wages of labour, but that which lowers the necessities of the labourer. But nobody will pretend to say that there is any thing in the monopoly of the colony trade, which has any tendency to lower the price of the necessities of the labourer. It is, therefore, impossible that the monopoly of the colony trade can raise the profits of stock. By those who are acquainted with the profound reasonings of Mr Ricardo, in proof of the two premises, this argument will be seen to be complete. There is not a demonstration in Euclid, in which the links are more indissoluble. To those who are not acquainted with those reasonings, we are aware that the pro-

COLONY.

Colony. positions will appear mysterious; and yet, we are afraid that, in the few words to which we are confined, it will not be possible to give them much satisfaction.

With regard to the last of the two propositions, that nothing can lower the wages of labour, but that which lowers the necessaries of the labourer, we may confine ourselves to that combination of circumstances which marks the habitual state, without adverting to the modifications exemplified in those states of circumstances which are to be regarded as exceptions. The habitual state of population is such, that wages are at the lowest terms; and cannot be reduced lower without checking population, that is, reducing the number of labourers. In this case, it is self evident, that nothing can lower the wages of labour, but lowering the necessaries of the labourer. In all, then, except the extraordinary cases, which it would require too many words here to explain, in which a country is but partially peopled, and in which part of the best land is still unemployed, the proposition of Mr Ricardo is indisputable, that nothing can lower the wages of labour except a fall in the necessaries of the labourer.

Let us next consider the proposition, That nothing can raise the profits of stock but that which lowers the wages of labour.

One thing is perfectly clear, that if the whole of what is produced by the joint operations of capital and labour, were, whatever it is, divided, without deduction, between the owner of the stock, and the labourers whom it employs, in that case, whatever raised the wages of labour, would lower profits of stock, and profits of stock could never rise except in proportion as wages of labour fell. The whole being divided between the two parties, in whatever proportion the one received more, it is certain that the other would receive less.

But what is here put in the way of supposition, viz. that the whole of what is produced by the joint operations of capital and labour is divided between the capitalists and the labourers, is literally and rigidly the fact. It is, then, undeniable, that nothing can raise the profits of stock, but that which lowers the wages of labour.

The whole produce, without any exception, of every country, is divided into three portions, rent, wages, and profits. If there were no rent, and the whole were divided into profit and wages, the case would be clear; because nothing could be added to the one without being detracted from the other.

Rent, however, does, in reality, make no difference. Rent is no part of the joint produce of labour and capital. It is the produce, exclusively, of a particular degree of fertility in particular lands; and is yielded over and above a return to the whole of the labour and capital employed upon that land, over and above a return equal to the joint produce of an equal portion of labour and capital in any other employment.

So much, then, for Dr Smith's opinion, that the monopoly of the colonial trade raises the profits of stock. Let us next inquire if it be true, that a rise in the profits of stock, if it were produced by the monopoly, would occasion, as he supposes, any dis-

couragement to the foreign trade of the mother country.

It would occasion this discouragement, he says, by raising prices. If, then, it can be shown, that it would certainly not raise prices, every reason for supposing that it would afford any discouragement to foreign trade is taken away. But that a high rate of profits does not and cannot raise prices, is evident from what has been deduced above. The whole produce of the joint operations of labour and capital being divided between profit and wages, in whatever degree profit rises, wages fall; the cost of production remains the same as before.

Not only does a variation in the state of wages and profit give no obstruction to foreign trade, a variation even in the cost of production gives no obstruction. A nation exports to another country, not because it can make cheaper than another country; for it may continue to export, though it can make nothing cheaper. It exports, because it can by that means get something cheaper from another country than it can make it at home. But how can it, in that case, get it cheaper, than it can make it at home? By exchanging for it something which costs it less labour than making it at home would cost it. No matter how much of that commodity it is necessary to give in exchange. So long as what it does give is produced by less labour, than the commodity which it gets for it could be produced by at home, it is the interest of the country to export. Suppose that the same quantity of corn which is produced in England by the labour of 100 men, England can purchase in Poland with a quantity of cotton goods which she has produced with the labour of 90 men; it is evident that England is benefited by importing the corn and exporting the cotton goods, whatever may be the price of the cotton goods in Poland, or the cost of producing them. Suppose that the cotton goods could be produced in Poland with the labour of 85 men, that is, less than they are supposed to be produced with in England. Even that would not hinder the trade between them. Suppose that the same quantity of corn, which is raised in England with the labour of 100 men, is raised in Poland with the labour of 80; in that case, it is plain, that Poland can get with 80 men's labour, through the medium of her corn, the same quantity of cotton goods which would cost her the labour of 85 men, if she was to make them at home. Both nations, therefore, profit by this transaction; England, to the extent of 10 men's labour, Poland to the extent of 5 men's labour; and the transaction, in a state of freedom, will be sure to take place between them, though England is less favourably situated than Poland with regard to both articles of production.

In what manner this class of transactions are affected by the intervention of the precious metals: in what manner the precious metals distribute themselves, so as to leave the motives to this barter exactly the same as they would be, if no precious metal intervened, it would require too many words here to explain. The reader who recurs for that explanation to Mr Ricardo, the first author of it, will not lose his time or his pains.

One other disadvantage of the colony trade is ad-

Colony.

duced by Dr. Smith. It turns the capital of the country out of a more into a less profitable employment, by turning it from the home to a foreign trade, from a foreign of quick to a foreign of slow returns, and from a foreign to a carrying trade. This doctrine, too, requires some explanation, and more, to be sufficiently clear, than can here be bestowed upon it. The home trade is not necessarily more advantageous than the foreign, nor the foreign of quick than the foreign of slow returns, nor any of them all than the carrying trade. These trades, it may be allowed, increase the gross produce of a country, in the order in which Dr. Smith has arranged them. But a country is happy and powerful, not in proportion to its gross, but in proportion to its net revenue, not in proportion to what it consumes for the sake of production, but to what it has over and above the cost of production. This is an important fact, which, in almost all his reasonings, Dr. Smith has overlooked. It will hardly, however, be denied, that in various circumstances, any one of these trades, the carrying trade itself, may be more conducive to a net revenue than any of the rest; and in a state of freedom will be sure to be so, as often as the interest of individuals draws into that channel any portion of the national stock.

We have now, therefore, considered all those cases which, in the study of colonial policy, can be regarded in the light of *species* or classes. There are one or two singular cases, which are of sufficient importance to require a separate mention.

Value of Colonies in reference to the Navy examined

That English law, which establishes the monopoly of the colonies, at least of the transatlantic ones, professes to have in view, not trade so much as defence. The reason of that round-about policy is, in this manner, deduced. The defence of England stands very much upon her navy; her navy depends altogether upon her sailors; the colony trade and its monopoly breeds sailors; therefore, colonies ought to be cultivated, and their trade monopolized.

Upon the strength of this reasoning, in which, for a long time, it would have appeared to be little less than impiety to have discovered a flaw, the navigation laws, as they are called, were embraced, with a passionate fondness, by Englishmen.

Nothing is worthy of more attention, in tracing the causes of political evil, than the facility with which mankind are governed by their fears; and the degree of constancy with which, under the influence of that passion, they are governed wrong. The fear of Englishmen to see an enemy in their country has made them do an infinite number of things, which had a much greater tendency to bring enemies into their country than to keep them away.

In nothing, perhaps, have the fears of communities done them so much mischief, as in the taking of securities against enemies. When sufficiently frightened, bad governments found little difficulty in persuading them, that they never could have securities enough. Hence come large standing armies; enormous military establishments; and all the evils which follow in their train. Such are the effects of taking too much security against enemies!

A small share of reflection might teach mankind,

Colony.

that in nothing is the rigid exercise of a sound temperance more indispensable to the well-being of the community than in this. It is clear to reason (alas, that reason should so rarely be the guide in these matters!) that the provision for defence should always be kept down to the lowest possible, rather than always raised to the highest possible, terms! At the highest possible terms, the provision for defence really does all the mischief to a community which a foreign enemy *could* do; often does a great deal more than it *would*. A moderate provision against evils of frequent and sudden occurrence, a provision strictly proportioned to the occasion, and not allowed to go beyond it, will save more evil than it produces. All beyond this infallibly produces more evil than it prevents. It enfeebles by impoverishing the nation, and degrading by poverty and slavery the minds of those from whom its defence must ultimately proceed; and it makes it, in this manner, a much easier prey to a powerful enemy, than if it had been allowed to gather strength by the accumulation of its wealth, and by that energy in the defence of their country, which the people of a well-governed country alone can evince.

A navy is useful for the defence of Great Britain. But a navy of what extent? One would not, for example, wish the whole people of Great Britain engaged in the navy. The reason, we suppose, would be; because this would not contribute to strength, but weakness. This is an important admission. There is, then, a line to be drawn; a line between that extent of navy which contributes to strength, and that extent which, instead of contributing to strength, is sure to produce weakness. Surely it is a matter of first rate importance to draw that line correctly. What attempt has ever been made to draw it at all? Can any body point out any land-marks which have been set up by the proper authority? Or, has the matter been always managed without measure or rule? And has it not thus always been an easy task to keep the navy in a state of excess; always beyond the line which separates the degree that would contribute to strength from the degree that infallibly contributes to weakness?

As the passion of England has always been to have too great a navy: a navy, which, by its undue expense, contributed to weakness; so it has been its passion to have too many sailors for the supply of that navy. The sailors of a navy are drawn from the sailors of the maritime trade. But a navy of a certain extent requires, for its supply, a maritime trade of only a certain extent. If it goes beyond that extent, all the excess is useless, with regard to the supply of the navy. Now, what reason has ever been assigned to prove, that the maritime traffic of Great Britain would not, without the monopoly of the colonies, afford a sufficient supply of sailors to a sufficient navy? None, whatsoever: none, that will bear to be looked at. But till a reason of that sort, and a reason of indubitable strength, is adduced, the policy of the navigation laws remains totally without a foundation. In that case, it deserves nothing but rejection, as all the world must allow. It is a violent interference with the free and natural course of things;

Colony. the course into which the interests of the community would otherwise lead them; without any case being made to appear which requires that violent disturbance.

The discussion of this supposed benefit of colonies, we shall not pursue any farther; for, as a signal proof of the diffusion of liberal ideas, the policy of the navigation laws has become an object of ridicule, with hardly any defenders, in the British Parliament, as the debates of the last session happily evince.

Case of Mining Colonies examined.

There is another singular case, created by mines of the precious metals. A colony may be formed and retained for the sake of the gold and silver it may produce. Of this species of colony we have something of a specimen in the Spanish colonies of Mexico and Peru. The question is, whether any advantage can ever be derived from a colony of this description? The answer to this question is not doubtful; but it is not very easy, within the limits to which we are confined, to make the evidence of it perfectly clear to every body. In one case, and in one case alone, an advantage may be derived. That is the case, in which the colony contains the richest mines in the world. The richest mines in the world always, in the case of the precious metals, supply the whole world; because, from those mines, the metals can be afforded cheaper, than the expence of working will allow them to be afforded from any other mines; and the principle of competition soon excludes the produce of all other mines from the market.

Now, the country, which contains the richest mines, may so order matters, as to gain from foreign countries, on all the precious metals which she sells to them, nearly the whole of that difference which exists between what the metal in working costs to her, and what, in working, it costs at the mines, which, next to hers, are the most fertile in the world.

She must always sell the metal so cheap, as to exclude the metal of those other mines from the market; that is, a trifle cheaper than they can afford to sell it. But, if her mines are sufficiently fertile, the metal may cost her much less in working than the price at which she may thus dispose of it. All the difference she may put in her exchequer. In three ways this might be done. The government might work the mines wholly itself: It might let them to an exclusive company: It might impose a tax upon the produce at the mine. In any one of these ways it might derive a sort of tribute from the rest of the world, on account of the gold and silver with which it supplied them. This could not be done, if the mines, without being taxed, were allowed to be worked by the people at large; because, in that case, the competition of the different adventurers would make them undersell one another, till they reduced the price as low as the cost of working would allow. Could the tax at the mine be duly regulated, that would be the most profitable mode; because the private adventurers would work the mines far more economically, than either the government or an exclusive company.

It is evident that this is a mode of deriving advantage from the possession of the richest mines of the precious metals, very different from that which was

Colony. pursued by the Spanish government, and which has been so beautifully exposed by Dr Smith. That government endeavoured to derive advantage from its mines, by preventing other countries from getting any part of their produce, and by accumulating the whole at home. By accumulating at home the whole of the produce of its mines, it believed (such was the state of its mind) that Spain would become exceedingly rich. By preventing other countries from receiving any part of that produce, it believed that it would compel them to continue poor. And, if all countries continued poor, and Spain became exceedingly rich, Spain would be the master of all countries.

In this specimen of political logic, which it would not be difficult to match nearer home, there are two assumptions, and both of them false: In the first place, that a country can accumulate, to any considerable extent, the precious metals; that is, any other way than by locking them up and guarding them in strong-holds: In the next place, that, if it could accumulate them, it would be richer by that means.

The first of these assumptions, that a country can keep in circulation a greater proportion than other countries of the precious metals, "by hedging in the cuckoo," as it is humourously described by Dr Smith, has been finely exposed by that illustrious philosopher, and requires no explanation here.

On the second assumption, that a country, if it could hedge in the precious metals, would become richer by that process, a few reflections appear to be required.

It is now sufficiently understood, that money, in any country, supposing other things to remain the same, is valuable just in proportion to its quantity. Take Mr Hume's supposition; that England were walled round by a wall of brass twenty miles high; and that the quantity of her money were, in one night, by a miracle, either raised to double, or reduced to one half: In the first case, every piece would be reduced to one half of its former value; in the second case, it would be raised to double its former value, and the value of the whole would remain exactly the same. The country would, therefore, be neither the richer nor the poorer; she would neither produce more nor enjoy more on that account.

It is never then by *keeping* the precious metals, that a country can derive any advantage from them; it is by the very opposite, by *parting with* them. If it has been foolish enough to hoard up a quantity of the produce of its capital and labour in the shape of gold and silver, it may, when it pleases, make a better use of it. It may exchange it with other countries for something that is useful. Gold and silver, so long as they are hoarded up, are of no use whatsoever. They contribute neither to enjoyment nor production. You may, however, purchase with them something that is useful. You may exchange them either for some article of luxury, and then they contribute to enjoyment; or you may exchange them for the materials of some manufacture, or the necessities of the labourer, and then they contribute to production; then the effect of them is to augment the riches, augment the active capital, augment the annual produce of

Colony.

the country. So long as any country hoards up gold and silver, so long as it abstains from parting with them to other countries for other things, so long it deprives itself of a great advantage.

Cause of the desire to possess Colonies.

If colonies are so little calculated to yield any advantage to the countries that hold them, a very important question suggests itself. What is the reason that nations, the nations of modern Europe at least, discover so great an affection for them? Is this affection to be *wholly* ascribed to mistaken views of their utility, or partly to other causes?

It never ought to be forgotten, that, in every country, there is "a Few," and there is "a Many;" that in all countries in which the government is not very good, the interest of "the Few" prevails over the interest of "the Many," and is promoted at their expence. "The Few" is the part that governs; "the Many" the part that is governed. It is according to the interest of "the Few" that colonies should be cultivated. This, if it is true, accounts for the attachment which most of the countries, that is, of the governments of modern Europe, have displayed to colonies. In what way it is true, a short explanation will sufficiently disclose.

Sancho Panza had a scheme for deriving advantage from the government of an island. He would sell the people for slaves, and put the money in his pocket. "The Few," in some countries, find in colonies, a thing which is very dear to them; they find, the one part of them, the precious matter with which to influence; the other, the precious matter with which to be influenced;—the one, the precious matter with which to make political dependents; the other, the precious matter with which they are made political dependents;—the one, the precious matter by which they augment their power; the other, the precious matter by which they augment their riches. Both portions of the "ruling Few," therefore, find their account in the possession of colonies. There is not one of the colonies but what augments the number of places. There are governorships and judgeships, and a long train of *et ceteras*; and above all, there is not one of them but what requires an additional number of troops, and an additional portion of navy,—that is of great importance. In every additional portion of army and navy, beside the glory of the thing, there are generalships, and colonelships, and captainships, and lieutenantships, and in the equipping and supplying of additional portions of army and navy, there are always gains, which may be thrown in the way of a friend. All this is enough to account for a very considerable quantity of affection maintained towards colonies.

But beside all this, there is another thing of still greater importance; a thing, indeed, to which, in whatever point of view we regard it, hardly a thing else can be esteemed of equal importance. The colonies are a grand source of wars. Now wars, even in countries completely arbitrary and despotical, have so many things agreeable to the ruling few, that the ruling few hardly ever seem to be happy except when engaged in them. There is nothing to

which history bears so invariable a testimony as this. Nothing is more remarkable than the frivolous causes which almost always suffice for going to war, even when there is little or no prospect of gaining, often when there is the greatest prospect of losing by it, and that, even in their own sense of losing. But if the motives for being as much as possible in war are so very strong, even to governments which are already perfectly despotical, they are much stronger in the case of governments, which are not yet perfectly despotical, and of governments of which the power is still, in any considerable degree, limited and restrained.

There is nothing in the world, where a government is, in any degree, limited and restrained, so useful for getting rid of all limit and restraint, as wars. The power of almost all governments is greater during war than during peace. But in the case of limited governments, it is so, in a very remarkable degree.

In the first place, there is the physical force of the army, and the terror and awe which it impresses upon the minds of men. In the next place, there is the splendour and parade, which captivate and subdue the imagination, and make men contented; one would almost say happy, to be slaves. All this surely is not of small importance. Then there is an additional power with which the government is entrusted during war. And, far above all, when the government is only limited by the will of a certain portion of the people, as under the British government; by the will of those who supply with members the two houses of Parliament, war affords the greatest portion of the precious matter with which that will may be guided and secured. Nothing augments so much the quantity of that portion of the national wealth which is placed at the command of the government, as war. Of course, nothing puts it in the power of government to create so great a number of dependents, so great a number of persons, bound by their hopes and fears, to do and say whatever it wishes them to do and say.

Of the proposition, that colonies are a grand source of wars, and of additional expence in wars; that expence, by which the ruling few always profit at the cost of the subject many; it is not probable that much of proof will be required.

With regard to additional expence, it can hardly appear to be less than self-evident. Whenever a war breaks out, additional troops, and an additional portion of navy, are always required for the protection of the colonies. Even during peace, the colonies afford the pretext for a large portion of the peace establishment, as it is called,—that is, a mass of warlike apparatus and expence, which would be burdensome even in a season of war. How much the cost amounts to, of a small additional portion, not to speak of a large additional portion, of army and navy, Englishmen have had experience to instruct them; and how great the mischief which is done by every particle of unnecessary expence, they are daily becoming more and more capable of seeing and understanding.

That the colonies multiply exceedingly the causes and pretexts of war, is matter of history; and might have been foreseen, before reaping the fruits of a bitter experience. Whatever brings you in contact

Colony.

with a greater number of states, increases, in the same proportion, those clashings of interest and pride out of which the pretexts for war are frequently created. It would exhibit a result, which probably would surprise a good many readers, if any body would ex-

amine all the wars which have afflicted this country, from the time when she first began to have colonies, and show how very great a proportion of them have grown out of colony disputes. (P. 7.)

COMMERCE.

As the *history of Commerce* has been already given in the body of the work, and, as the discussion of its nature and principles must necessarily be resumed in our article on *POLITICAL ECONOMY*, we mean, at present, to confine ourselves to a very brief exposition of the leading doctrine of that Science in regard to Trade, and to some practical discussions, which seem to find a fitter place here than in any other article. Our more general remarks, then, will relate chiefly to the nature and effects of that very erroneous system of Political Economy, commonly called the *Mercantile System*; and those of a more practical kind will be directed to the consideration of the profits of trade—of those transactions called *speculations*—of the effects of trade upon individual views of national policy—of the effects of long credit—and of the consequences that would result to commerce from the abolition of the restrictive statutes regarding interest of money.

View of the
Mercantile
System.

I. The basis of the *Mercantile System*, which, though long relinquished by Political Economists, still retains an influence both on Merchants and Statesmen, is, that “wealth consists in the precious metals; that what is gained in trade by one nation must be lost by another; and that our great object in receiving returns should be to get money instead of merchandise.” It followed from such notions, that of all possessions, a mining country, such as Mexico and Peru, was the most desirable; hence, in a great measure, our war with Spain, in 1740, which led to our unfortunate expedition to Cartagena, involved us in a contest with France, and caused us, in the course of eight years, an immense waste of blood and treasure.

Though we failed in our favourite object, the influence of the mercantile system continued, and was singularly favoured by the annual statement of custom-house returns. These returns exhibit an apparent excess of exports above imports, and give rise to the notion that the balance is sent over in the shape of money. Supposing the exports of England to the Continent of Europe to amount for any given year to £20,000,000, and the imports to £14,000,000, the difference (£6,000,000) is, according to this absurd notion, the amount of profit paid to us in money. It is clear, however, that the custom-house returns take no notice of some very important items, such as the export of public money for our foreign garrisons, the transmission of bills of exchange to foreign merchants, or the import of smuggled goods. Besides, if the *quantum* of our circulating medium remain, as it probably does, very nearly on a par, what becomes of the supposed importation of money? Were England in possession of

all the annual balances which the advocates for this system suppose her to have received in money during the last century, our metallic stock would not be below £400,000,000 Sterling; that is, ten times its actual amount!

When a merchant exports goods, the sale, of course, takes place abroad, and a remittance is made, either by bill or by the return of other merchandise. It hardly ever enters into the contemplation of the exporter that he would find an advantage in obtaining a return in coin or bullion. Money owes the reputation it has acquired, as an object of national interchange, to its convenience in other points; to its being the commodity with which we regularly go to market, and to its fitness for the smallest purchases by the minuteness of its subdivisions. But this recommendation, however important in private business, should have no weight in the intercourse of nations: Merchants can be at no loss to dispose of a remittance made in the shape of goods, nor is it any object with them to multiply the means of petty purchases.

The interest of a commercial country is not to increase the amount of its currency, but to quicken its circulation; the same sum performing double and triple duty when passed expeditiously from hand to hand. Now, nothing promotes circulation so much as exemption from arbitrary interferences, were the effect nothing more than the general preservation of credit. In France, the monstrous abuse made of the paper system in the beginning of the Revolution has long prevented the use of any other circulating medium than coin; the result is an annual loss of *three millions sterling* to the public, such being the difference between the cost of paper and the precious metals, even after making allowance for the retention of a portion of the latter sufficient for the purposes of banking.

Some people, however, imagine that, to increase the amount of the circulating medium, is to increase the capital of a country. These persons should recollect that capital is by no means limited to money, but embraces all that mass of property which is devoted to reproductive consumption. When we wish to lend capital, or to employ it in business, we begin by selling the various articles at our disposal; the amount is then in our hands in the shape of money; but this is very transient; the money disappears as soon as we make payment for the new purchases. The public, not having time to enter into all this reasoning, judge from first impressions, and take for granted that money is capital, because its agency is required to put capital in motion. Governments, however, might have saved themselves much trouble in providing supplies of metallic currency; since the na-

Commercial course of business will invariably provide them for itself. The plenty or scarcity of the precious metals depend on considerations altogether different from the imagined balance of trade. Specie was so scarce in England in 1809, that Government was not a little embarrassed to find £200,000 for the Walcheren expedition; yet in that year our custom-house returns presented an apparent balance of above £7,000,000 in our favour.*

We must not, however, be understood as advancing that the state of mercantile transactions has at no time had an influence on the course of exchange: the great import of corn in 1810 certainly lowered it materially; but this was owing to an extraordinary circumstance—the non-convertibility of our paper money. Had our circulating medium been such as to admit of exportation, and to possess currency on the Continent, the extra imports would have but slightly affected the rate of exchange.

Losses to
England
from Mer-
cantile Sys-
tem.

No country has suffered so much from the errors of the mercantile system as England; partly on account of the influence of traders and manufacturers in our legislature; partly from the temporizing policy of our ministers, who have seldom scrupled to buy the consent of any great body of the community to a new tax by the grant of some injurious preference. Hence a variety of pernicious regulations in favour of the landed, the shipping, and the manufacturing interests; hence, also, a number of unfortunate measures in our foreign policy.

Our ancestors laid it down as a fundamental rule, that there could be no profit on the one hand, without a corresponding loss on the other. They considered trade as a game of mere transfer, and had no idea how a country could derive wealth by an intercourse, however actively or however skilfully kept up, between its own inhabitants. Charles II. entered on the war of 1672 with high hopes, imagining that, by destroying the commerce of Holland, we should not only increase our own, but in a manner absorb that of the world. Political reasons led us afterwards into close alliance with Holland, and prevented the ebullitions of our jealousy in that direction; but the alarming power of Louis XIV. and the prospect of his acquiring the crown of Spain, led us to a closer connection with Portugal, and particularly to the well-known Methven treaty, concluded in 1703, the object of which was to favour the consumption of port wine, in return for a similar preference to our manufactures. The result has been, that we have not scrupled, for more than a century, to punish our palates and injure our health for the sake of an imaginary political advantage; we say imaginary, because France would evidently have agreed to take our manufactures in return for her produce; and if the increase of her trade had, on one hand, the effect of augmenting, to a certain extent, her national power, it would, on the other, have increased her dependence on us, and have rendered a war with us extremely impolitic and unpopular.

Our attachment to Portugal arose, in a great measure, from her not being a manufacturing country,

and likely, in the opinion of the calculators of the day, to be so much the more advantageous to us in the capacity of a customer. This notion has prevailed in our councils to a very recent period; the Administration of 1808 and 1809, not scrupling to give encouragement to the export of merchandise, on a large scale, to the unproductive occupants of Brazil and Spanish America. Now, the fact is, that the means of extending our trade, and consequently our profits, with a foreign country, are to be estimated by a quite opposite rule; they depend on the productive power of that country,—on its means of affording equivalents for our commodities; in other words, on its capability of paying for that which it suits us to sell to it. Now, what country was ever wealthy without industry? The mines of Mexico and Peru, the richest the world ever saw, fall, in point of annual produce, far short of the annual value of the cotton, the tobacco, the flour, and other less tempting products of the United States. In like manner, the cochineal, the cocoa, the barilla, and even the indigo of Spanish America, form a small amount when put in competition with the exchangeable commodities possessed by the industrious nations in our own neighbourhood, such as France, the Netherlands, or the North of Germany.

If from our own favourite policy we turn our attention to that of continental states, we find Holland steering a course of impartiality, and guarded from an imitation of our trespasses, not indeed by superior knowledge, but by the characteristic moderation of her government. The northern kingdoms deserve comparatively little attention, their rulers having in general given their thoughts much more to war than to discussions of internal policy. The same thing was long true of a country where the commercial interest has at no time been very considerable; the personal will of the Sovereign, and the influence of the *Noblesse*, having afforded the grand *raisons determinantes* for public measures. Still the history of France is not without traces of the effects of mercantile prejudices: among other regulations of the kind, there formerly existed several for the purpose of favouring linen manufactures instead of cotton, because flax was a home product, while the purchase of cotton carried money out of the country.

Mercantile
Policy of
other Coun-
tries.

At last, it was found out by some Frenchmen of greater sagacity than the rest, that cotton might be safely admitted to entry, the money required to buy it proceeding necessarily from the employment of French industry in some shape or other. But the extent of popular prejudice was most singularly exemplified at the time when it was proposed to permit the unrestrained use of *toiles peintes*, or printed calicoes: every town that had a chamber of commerce remonstrated against it. A deputation sent from Rouen affirmed, that “the proposed measure would throw its inhabitants into despair, and make a desert of the surrounding country.” Lyons, the centre of the silk manufacture, declared that “the news had spread terror into all its workshops.” Tours

COMMERCE.

Commerce. "foresaw a commotion likely to cause a convulsion in the body politic;" Amiens asserted that "the proposed act would become the tomb of the manufacturing industry of France;" and Paris declared that "her merchants came forward that they might bathe the throne with their tears." The Government, however, stood firm, the duty on printed calico was withdrawn, and the Inspector General of Manufactures ventured some time afterwards to challenge the authors of these eloquent effusions to compare their predictions with the result. "Will any of you," he said, "deny that the manufacture of painted calico has been the cause of giving a vast extension to the industry of the country, by employing a number of hands in spinning, weaving, bleaching, and printing? Look only to the branch of dyeing, and say whether this change has not done more for it in a few years than other manufactures would have accomplished in a century." Say, *Traité d'Economie Politique*, Book I. chap. xvii.

In some countries Government goes much farther, and still acts in a commercial or manufacturing capacity, notwithstanding all the admonitions of political economists, or the more home felt lessons of experience. The Austrian Government conducts the gold and silver mines of Hungary, and to so little account, that the profit realized from these splendid establishments does not exceed a few thousands a-year. (See Dr Clarke's *Travels*, Vol. IV.) So lately as last summer (June 1817), the French Government, desirous of laying in a stock of corn for Paris, obtained a loan of money, with which they made purchases in the various markets both in and out of the kingdom. The result was most distressing; the price of corn rose from 80s. to 120s. per quarter. The people in the provincial towns became apprehensive of a scarcity, and though in general submissive to a fault, attempted at Rouen, and other places, to impede the course of the market, and to prescribe a limit to the price of corn. The alarm once given extended throughout all Europe, and gave occasion to a sudden rise, as may be seen by a reference to the corn prices at the time in London, Amsterdam, and Hamburgh. Nothing, therefore, is more impolitic than the interference of the public treasury with markets, however good the motive; a truth which has been so thoroughly felt in England as to prevent anything of the kind during the last twenty-five years; Government having confined itself, in seasons of scarcity (as 1795, 1800, 1810), to granting an extra bounty on the import of corn.

We are next to advert to the mercantile system in its most limited sense, in the shape which it now bears, after all the modifications of the experience of a century and a half. The predilection for the import of "hard dollars" has disappeared among a portion of the public, particularly since making the discovery that bank paper can be made to answer the purposes of gold and silver. But even these persons are far from admitting the doctrines of political economists in all their extent; they still cling to the notion that we should discourage the import of foreign produce whenever a corresponding commodity can be raised at home; that we should impede or even prohibit all foreign manufactures; and that we should not scruple to encourage certain

fabrics of our own by bounties. Such is still the creed of the great majority of our merchants and manufacturers; such was, till within these few years, the creed of our Ministers and Presidents of the Board of Trade. It proceeds on the plausible idea that we cannot provide too much employment, and that our people would be in danger of falling short of work were we to purchase finished articles at the hand of foreigners. But there is not in the natural course of things any such deficiency of labour as to make it necessary or even expedient for us to turn things out of their regular order, for the sake of giving employment to our population. Providence has evidently ordained that industry should be at no loss for objects; the interruptions to its peaceful course arise from our own wayward policy, from our restraints, prohibitions, and, above all, from our sudden changes from war to peace, and from peace to war. These are the true causes of such scenes of embarrassment and bankruptcy as we witnessed in 1793 at the close of profound peace, and as we now unhappily witness at the end of a long continued war.

Equally erroneous is the notion, that it is more for our interest to send abroad manufactures than raw produce or money. If you grant a bounty on an export, you do nothing more or less than bribe a foreigner to make a purchase from you; you withdraw from its natural destination a portion of your capital and labour; for the sake of extending one branch of business, you weaken your means of competition in others. The money so long paid in the shape of bounties on one of our most popular exports, we mean British linen under 1s. 6d. a yard, is a public loss not only to the extent in question, but to twice or three times that extent in indirect injury; it has withheld the industry of our countrymen from other lines which they might have prosecuted without a premium, and in which they would have had no occasion to dread the rivalry of their neighbours.

Mr Hume has justly remarked, that in a question of personal right, the perceptions of a half-educated man may be sufficiently sound, but that the case is very different in regard to matters of general policy, where the real is often different from the apparent result. Now, this state of half knowledge has been the origin of almost all our mercantile miscalculations; we have listened to first impressions, and have not scrupled to give them a practical operation by acts of Parliament, without ever considering that the remote consequences would be injurious to ourselves.

To what fatality is it then owing, that, in this mighty commercial country, the public should still be so far behind hand in the knowledge of the principles of trade? Unfortunately these doctrines, though closely connected with the national prosperity, have never formed an object of attention at the English Universities, and but indirectly and imperfectly in those to the northward of the Tweed. Add to this, that most of the works hitherto published on Political Economy, are written in an abstract, unattractive style, fatiguing the attention of the reader by a long series of reasoning, and seldom relieving him by diversity of subject, or by the introduction of practi-

Modified
State of the
Mercantile
System.

Commerce.

cal illustrations. The public is still in want of a work which should convey the liberal doctrines of the philosopher in the plain language of business, and support the course of reasoning by an appeal to facts familiar to the mind of the merchant. Our limits do not by any means admit of our supplying this deficiency, or of bringing forward the arguments necessary to erect a structure of conclusive reasoning: they have enabled us only to state some of the more important results, to which we shall now make a few additions.

Farther Ex-
position of
the true
Principles of
Commerce.

We may safely discharge from our minds all that has been said and all that has been written in regard to the greater relative advantage attendant in trading in this or that particular commodity: we may feel satisfied that profits are much more on an equality than is commonly supposed; that no one would long be a dealer in that which did not afford him advantage, or remain a stranger to that which was throwing an extra gain into the pockets of his neighbour. The same rule is applicable in a national sense, the traffic in one commodity being either directly or indirectly as productive of profit as in another. Even foreign articles of luxury should not be discouraged, since the money required to pay for them must be previously raised by the employment of British industry in some useful manner. This affords a new proof of the fallacy of first impressions, and leads to the grand practical conclusion of allowing people to "buy commodities wherever they can be got cheapest, without seeking to favour home produce above colonial or colonial above foreign."

Merchants should possess unrestricted freedom not only in regard to the articles they deal in, but in respect to the time of keeping them back or bringing them to market;—and this not only from the general title which every one has to the management of his own property, but from a conviction that whatever benefits the individual will be productive of corresponding benefit to the public. This is a point of the last importance, as reconciling the lower orders to a variety of unpopular employments of capital, such as buying up goods to be warehoused, and not brought to market till prices are advanced. Take, for instance, the capitalist who buys 1000 hhd. of sugar on its arrival from the West Indies in August, for the purpose of selling it in the succeeding March or April, such a transaction is of use to all parties; affording, in the first instance, a customer for the planter or planter's correspondent; a depository for the public during the season that the article ought in great part to be stored up; and finally a seller, at a time when, without such deposits and such forthcoming of supply, the price might have become exorbitant, and might have continued so until the arrival of the next year's crop. How applicable are these arguments to the most obnoxious of all traders,—the engrosser of corn!

The more we study the natural progress of commerce, the more we shall be satisfied of the expediency of leaving all its various agents to their uncontrolled management. Business then divides itself, particularly in a large city, into a variety of separate branches, each of which may be carried on to a surprising extent by separate establishments. The

commission charged by such persons is small, their dispatch extraordinary; capital does not remain locked up in their hands, and goods find their way to the market whenever prices are encouraging, that is, whenever the consumers are in want of them; they are withheld only when the market is glutted, and when to force sales would be productive of eventual injury to the buyers themselves. The doctrine of the happy medium is nowhere more applicable than in commerce: if you reduce prices for one season under what is necessary to indemnify the producer, you discourage production for the next, and you expose yourself to the hazard of a dearth.

Monopoly is now generally admitted to be highly impolitic; no new grants of the kind have been issued among us for many years, and every renewal of the charter of our principal existing association, has been marked by a diminution of its restrictive character. The public are now aware that a privileged company cannot make its purchases abroad on better terms than individuals, and that the chief operation of the privilege is to enhance the sale prices, or, in other words, to put money into the hands of a few at the expence of the nation. They are farther aware that the concerns of a large corporation cannot be managed with the minute economy and vigilance of the private merchant, and that its grand advantage lies in the intelligence and dexterity acquired by the transaction of business to a large extent by one establishment; an advantage of great importance, but which has nothing to do with the possession of exclusive privileges.

It is now about thirty years since the conclusion of our well known commercial treaty with France; a treaty which many on both sides of the channel were inclined to think particularly advantageous to us, and which certainly afforded a grand object of declamation to Bonaparte. The fact, however, is, that such treaties are good only in as far as they give general confidence to the merchants of both countries; whenever they go farther, and interfere by specific provisions, they are infallibly pernicious, and not the least so to the apparently favoured nation. It is a symptom of some promise in the present day that, though backed by all Europe, our ministers did not, in the treaties of either 1814 or 1815, go the length of imposing any restraints on the trade of France, but left things to their free course, subject only to such restrictions as might be deemed indispensable by either Government for the protection of particular branches of manufacture.

The final conclusions to be drawn from the principles of commerce are of the most comprehensive and beneficent nature. They teach us that every nation finds its account in the prosperity of its neighbours; that it would experience a corresponding suffering from their decline; that to aim at engrossing more trade than *naturally falls to our share*, is sooner or later injurious to ourselves; and that war, even when successful, is attended with the most serious losses. War turns to waste a large portion of our productive means; it leaves us oppressed with a ruinous burden in peace; it impedes the future extension of our exports, for the injury done to our neighbours recoils on ourselves; in

Commerce. short, it is so replete with evil to the public and individuals, as to be justifiable only in an extreme case, such as the defence of national independence or the overthrow of a tyrannical usurper.

Principles of Commerce, how far understood on the Continent. In point of knowledge of the great doctrines of political economy, Germany, or, to speak more properly, the Protestant part of Germany, in particular Saxony, may be said to take the lead of other countries on the Continent. The Dutch, however exemplary in their practical legislation, have little turn for speculative reasoning; the French have not patience to follow through its various links, a chain of philosophical deductions, but their admiration of whatever is humane or liberal, makes them wonderfully delighted with the brilliant conclusions of the science. They have the advantage of possessing in the work of Mr Say, already referred to, the best arranged general treatise that has hitherto appeared on the subject; and they are by no means ill prepared for a very extensive application of political improvements; such as the abolition of privateering, the repeal of all heavy duties on foreign goods, and the substitution of inland taxes for those custom-house imposts which impede the free communication of nations. The rest of Europe is so much in the dark, in regard to the great truths of political science, as to see merely through the medium of local governments: this is the case even in Italy, although that country can boast individuals of some note among the writers on the principles of commerce, and the reflecting turn of the people is favourable to such investigations.

Unfortunately, the condition of most countries, but particularly of Britain, is adverse to the speedy application of these simple and beneficent principles. Particular branches of trade are loaded with taxes which cannot be recalled; capital is invested in manufactures raised by means of bounties, which, however impolitic, ought not to be suddenly withdrawn, while, to throw open our ports to the unrestrained import of foreign merchandise, would lead to a general derangement of industry, unfitted as we at present are to withstand the cheaper labour of the Continent. It was admitted by all parties in Parliament in a late memorable debate (13th March 1817), that "unbounded freedom in trade was our true policy;" but it was urged, that to resort to such a course would overthrow too many private interests, and raise too general a clamour, to be practicable for many years. All that can be done in this embarrassing situation is to acknowledge the true system, to approximate to it gradually but surely, to renounce the errors of our ancestors, and, in point of taxation, to impose duties merely for the purpose of revenue, never with the view of encouraging any particular branch at the expence of another.

II. Having thus briefly stated the general doctrine of *Free Trade*, we shall proceed to the practical topics which we proposed to discuss; beginning with the consideration of the average profit of capital employed in trade.

1. It is common to estimate the emolument of a wholesale business in Britain, in a small established concern, at 10 *per cent.* on the capital;

moderate calculators will qualify this by calling it between 8 and 10 *per cent.*; but they who are at great pains to take every thing into the account, and to enumerate a variety of petty deductions which escape the sanguine reckoner, will find that in a large concern 7 *per cent.* is in general the extent of the clear earnings; leaving only 2 *per cent.* above that which has been the current rate of interest during the last twenty-five years. Mercantile profits are subject to a variety of unforeseen deductions, originating partly in an accumulation of petty expences, but more, at least in business of long credit, from deficient payments. The latter are technically called bad debts, and almost always exceed the anticipated amount, in consequence both of the sanguine temper of our countrymen, and of the actual capital of the buyers being much inferior to its appearance. Secrecy, both as to property and annual profit, is considered a first rate point among mercantile men; to the latter there can be no objection, but the concealment of the amount of capital, and the almost invariable consequence, its exaggeration, is productive of very pernicious effects. It is founded partly on the general vanity, and more, perhaps, on an expectation of direct advantage from the command of credit. But were the practice of transacting with ready money to become general, a merchant would have no greater motive to be thought in affluence than an individual in any other line. Be this as it may, the fact is, that the clear profits of trade, whether home or foreign, whether mercantile or manufacturing, whether retail or wholesale, are greatly below what the world imagines. Many hold a contrary language with regard to trade in general, but few do so in respect to their own particular business. "Ours," they say, "is of limited emolument, but other lines are very different, inasmuch as they admit of speculation and of higher charges." Whoever takes the trouble to question men in almost any business or profession, may reckon on receiving a succession of such answers,—answers not suggested by a wish to deceive or to conceal the profits of the individual, but originating in the general disposition to take the *omne ignotum pro magifico*. We dwell on this point from a desire to correct, as far as our influence goes, the prevalence of existing errors, and prepare our countrymen for the adoption of that patient and pains-taking course which was the basis of the prosperity of our ancestors, and which alone can extricate us from our present embarrassment. Some years ago, such language would not have been listened to; our minds were kept in a ferment by the fluctuations of war, property, whether in land, houses, or merchandise, had obtained an unexampled value; the majority of the possessors considered themselves the masters of assured fortunes, and never doubted that the general enhancement was in evidence of augmented national wealth.

Now that we have gained every political object, and that we know to our cost how far we are from enjoying internal prosperity, we are more disposed to give attention to the monitor who recalls the almost antiquated maxims of industry and economy, and who tells us, that, though we surpass our neighbours in activity and combination, we have much to

Commerce. learn from them, both in point of caution in enterprise, and of moderation in expenditure.

We are next to see how far these opinions are supported by official documents. The returns for the property-tax have of late afforded considerable means of ascertaining the circumstances of persons engaged in trade. If it be objected that many persons have not made a fair return, we may rejoin that, on the other hand, a number chose to conceal their disappointments from the world, and to pay the tax on an income they had not realized. The total number of *families* deriving an income from trade, manufacture, and professions, in England, Wales, and Scotland, is about 160,000:

120,000 of these returned their incomes under L. 150 a-year.

40,000 were above L. 150 a-year; and of these

3800 declared their income to exceed L. 1000 a-year.

Now, let any of our readers compare this statement with their previous ideas of the mercantile wealth of Great Britain, and they will bring to mind, if we are not much mistaken, an impression that the number of rich merchants throughout the empire greatly exceeded 3800. The total sum paid as property-tax under the head of the "profits of trade, manufactures, and professions," for 1814, was somewhat under 3½ millions, a sum certainly not to be paralleled in any other country, but falling considerably below the anticipation of Mr Pitt when he first introduced the income-tax so long ago as 1798.

We have naturally a strong disposition to contemplate the past or the distant through a magnifying medium, and to believe whatever the confident assertions of others, or the love of wonder in ourselves, suggests with regard to reported wealth. Hence the allegations so confidently brought forward in regard to the riches of ancient cities; hence the notion generally entertained with respect to the rapidity of fortune-making in our foreign settlements. India has long been proverbial in this respect, and it requires much more than the usual stock of information to discover, that if we make allowance for deaths and disappointments from various causes, the proportion of those who succeed in that country is not *greater than at home*; and that a fortune, when it does happen to be made, is the result of the length of time, of a habit of saving favoured by exemption from the expence of a family, of rare political contingencies, or, finally, of unusual opportunities consequent on the mortality of competitors. In point of trade few countries are more limited than India. In the West Indies, the field of industry is wider, particularly for planters, but the ratio of emolument has certainly not been greater, taking the whole of the last twenty years together, than in Great Britain. In support of these assertions, we appeal not to the young beginner, entering with sanguine hopes on his career, nor even to him who is advanced halfway in the eager pursuit, but to all who have passed a *length of years in these countries*, and who possess a sufficient share of reflection to turn their experience to account, by making a deliberate survey between the mother-country and her settlements. Particular instances may be given of the acquisition of mer-

cantile fortunes even in the last ten or twelve years, partly in India; and partly in Canada; but these have been rare, and the result of peculiar circumstances. Equal judgment and exertion have certainly been possessed by many merchants in the West India, American, and Continental branches; yet, we believe, that the whole list of these houses may be fairly challenged for an example of the *rapid* acquisition of fortune since the peace of Amiens.

Another point in which a similar delusion prevails, relates to the effects of war, particularly that of 1793; a war in which we still believe ourselves, and are believed by foreigners to have engrossed and absorbed the commerce of the world. A reference, however, to official documents will show that the exports and imports of the most boasted years of the war in question, were below the peace year 1802, and even below those of our late years of suffering. The flag of our enemies was indeed expelled from the Ocean, but the greater proportion of trade passed into the hands of neutrals: and, when in 1808, we took it out of their possession, we were taught, by dear bought experience, that war, under any circumstances, is adverse to commerce.

These observations must be understood not as intended to depreciate the value of commerce, or to damp the hopes of eventual success. They show indeed, that the *ratio* of profit is generally small, but they afford the consolatory assurance that mercantile concerns may be carried to a great extent, and that the amount of gain may, in process of time, be rendered very considerable. This leads us to advert to a matter of great interest to us as we now stand, relatively to the rival countries of the Continent. It is a maxim, that commercial establishments, whether in the mercantile or manufacturing line, should be confined to a few objects, and conducted on a large scale. It is by this only that the task of individuals can be simplified; that employment can be subdivided; that work can be put quickly through hands, or that we can provide on the spot a supply of the various and indispensable requisites of business. A large establishment affords the means of employment to every kind of capacity; in fact, the duty is so facilitated as to become, in many cases, a mere routine; while the more intelligent and attentive workmen act as superintendents, the mass of the unambitious and unthinking are occupied with the detail. It is owing to this process of subdivision, and to the relative magnitude of the London workshops, that many articles can be supplied in our metropolis as cheaply as in the provincial towns, where labour is 40 *per cent.* lower: the same rule accounts for the charge on the transaction of business by merchants, accountants, attornies, notaries, and agents, being less heavy than might be apprehended from the enormous expence of living in London. Similar results take place in regard to manufacture in favour of such towns as Birmingham, Sheffield, Manchester, Leeds; and it is to this, more than to any other cause, that we owe our ability to compete with the cheaper labour of the Continent.

2. This analysis of the profit of trade leads us to say a few words on a topic which has hitherto been very defined.

Commerce generally misunderstood, we mean the profits of speculation. That term is confined, by politico-economical writers, to the purchase of an article at a given time, with profit. Among men of business, however, this expression has a much more extended significance, and is applied, generally, to incurring extensive hazards of any kind in the hope of extensive emolument; in short, to whatever is foreign to the proper business of the individual, or beyond the control of common rules. It is to such undertakings that vulgar credulity ascribes extraordinary profits; and even well informed men are apt to give way to the assertions so confidently made, of vast occasional gains in this line of business. Dr Smith himself, after remarking (*Wealth of Nations*, Book I. chap. 10.), that to make a fortune in a regular line commonly requires a long life of industry and frugality, adds, no doubt on the faith of repeated assurances from mercantile friends, that there are many examples of fortunes realized by speculators in the course of a few years. Now, the men who embark in speculation are, in general, very loose accountants; their estimate of profits applies to the gross, never to the nett return; besides, they are almost always adventurers, and adventurers have seldom been noted for the observance of truth. Their favourite season of activity is a time like that of 1808, when the sudden stoppage of ordinary intercourse caused a rapid fluctuation in the prices of commodities, and when the regular merchants withdrew from the scene. Now, what sober estimate can be formed of loss or gain in such a chaos? Add to this that these men trade almost always on credit, and in need of all the support which flattering representations, and rumours of sudden profit, can give them. All these reasons seem to justify a deliberate inquirer in doing what is very seldom done in such occasions, we mean in withholding his belief from the confident allegations of speculators, so long as they are not supported by collateral evidence.

Our opinion is, that, instead of the large profits commonly ascribed to this course of trade, it will be found that the individuals concerned in it experience little else than disappointments, and maintain a perpetual struggle to keep up a fair appearance to the world. This opinion is founded partly on a knowledge of the actual career and circumstances of speculators, but more on the well known fact, that almost every line of business is in the hands of established merchants, who, of course, are too vigilant to overlook the opportunity of emolument, and who have much better means of information than temporary interlopers. Still, should there remain doubts as to the accuracy of our opinion, the question may be brought to a point by a reference to the account-books of any given number of celebrated speculators: their affairs end almost always in bankruptcy; their papers continue

open to access for years in the hands of their solicitors or assignees; and we are much mistaken if an inspection of them would show, in one case out of ten, that the parties had at any period succeeded in making their boasted profits.

We have been induced to dwell the more on the boasts of speculators, because they are productive of the greatest mischief in unsettling persons in business, particularly young men, and in making them look on their proper line with comparative contempt. It would be endless to attempt an enumeration of the various ways in which the rage for speculation has brought misfortune on our merchants and manufacturers. The opening of a new country, such as Buenos Ayres, Brazil, or Caraccas, has led to the export not only of a prodigious overstock of merchandise fitted for the country, but of many articles totally unsuited to the climate and habits of the people.*

Again, when the late war was drawing to a close, goods, both colonial and manufactured, were poured into the Continent of Europe, as if the market were inexhaustible, and as if the calamities of war had produced no decrease of disposable capital. At home, also, vast sums have been lavished in buildings, in mines, manufactories, and other establishments which never had a fair prospect of success, and owed their origin to the sanguine imagination of one projector, and the credulity of another.

The result of all this is, that hitherto our trading concerns have been very frequently mismanaged; that a great deal of property has been wasted by the inexperienced and sanguine; and that those who really expect to succeed in business must lay their account with submitting not only to a deal of labour, but of self-denial, in resisting the temptation of flattering projects, out of their own line. What a beneficial result would be produced were young merchants to adopt it as a rule not to listen to the ardent suggestions of persons of their own time of life, but to recur, on every question of consequence, to the advice of their seniors; of men who have had to make their own way in the world, and who, without perhaps possessing the advantage of education, or the talent of moulding their reasoning into the form of general principles, will still be found safe counsellors in the practical part of the business. If the result of their admonitions be to abridge some of the pleasing illusions of the mercantile beginner, is it not better that the true nature of his prospects should be made known to him in the early part of life? A deduction from anticipated enjoyment is a trifling sacrifice in comparison with the distress produced by failure in latter years, when the individual is less able to contend with difficulty, and has probably to provide for a family. Let any one extensively acquainted with mercantile men, call to recollection the situation of the majority of his

* Elegant services of cut glass were sent out to men accustomed to drink out of a horn or a cocoa-nut shell; skates were forwarded to a country where ice was unknown; and tools with a hatchet on one side, and a hammer on the other, to break the rocks, and cut the precious metals from them, as if the inhabitant had merely to go to the mountains, and cut down gold and silver by wholesale.—*Mawe's Travels to Brazil*.

Commerce. personal friends during the last twenty years, and say, whether any degree of self-denial would not be preferable to that succession of disappointments, anxieties, and losses, which have baffled the exertions and broken the spirits of so many meritorious persons.

The country in which trade has shone forth in all its splendour, where it has been cultivated without the support of arms or prohibitory regulations, where, in short, it has developed its beneficent tendency in all its extent, is Holland. If we look to the early enterprises of the Dutch, we find them enabled by the power of their productive industry to assert their independence at home, and to assail their enemies in the remotest part of their empire. The Portuguese in the east, and the Spaniards in the west, were each found unequal to the task of resisting these Republicans: a proud stand was made by them against the navy of England, and they did not fall into despair even when assailed by our forces in conjunction with those of France. Afterwards, when happily restored to our alliance, and when they concurred and cooperated with us in the great struggle against Louis XIV., it is surprising how large a proportion both of troops and subsidies was furnished by this apparently inconsiderable state. "No country," says Sir William Temple, "can be found where so vast a trade has been managed, yet the inhabitants have no native commodities towards building vessels, and hardly any that are considerable for traffic with their neighbours. Holland is grown rich by force of industry, by improvement and manufacture of foreign growths." Proceeding to specify more particularly the causes of this mercantile prosperity, Sir William enumerates "the easy communication of water, particularly by the Rhine and Maese; the security of property; the undisturbed liberty of conscience, and the progressive influx of people persecuted for their religious opinions in Flanders, England, France, and Germany." Such were the original causes; those of subsequent operation were the "general habit of industry and economy; the formation of canals; the institution of Banks; the low interest of money; the exemption of trade from imposts; the appropriation of particular towns to particular branches of business; application to the fisheries, and (what he regrets much should not exist in England) the practice of keeping an official register of all purchases of property;" a practice introduced into Holland and Flanders in the reign of Charles V. to the incalculable convenience and security of money transactions.

3. We are now to say a few words on a different topic,—the effects of trade in forming the character of individuals, a matter of no little importance in a country like ours, where merchants both constitute so large a portion of the community, and exercise such influence on the proceedings of Government. The mercantile character has a number of good points, being exempt from the vacuity and indecision so frequent in fashionable life, as well as from the various vices consequent on the habit of idleness, and which are so strikingly exemplified in the gaming and libertinism of the French metropolis. Whatever good is produced by continued activity and by a

Commerce. pointed attention to the specific objects of one's occupation, may be confidently looked for among commercial men; with the farther advantage, in large concerns, of an exemption from petty jealousies and invidious interferences. In such cities as London and Amsterdam, merchants become aware, less by a process of reasoning than by the continued result of experience, that the field is ample for all; that the prosperity of one is very far from impeding that of others; and that when disappointment and failure occur, their origin is to be sought in a very different cause from competition. Here, however, we must close our encomium; and, in the spirit of impartiality, proceed to exhibit the opposite side of the picture. The merchant's knowledge is particular, not general; he obtains a habit of understanding individual character, and a dexterity in managing his own affairs; but he has not, and cannot, from his course of occupation, acquire the power of reasoning comprehensively on the interests of trade. He is, accordingly, a very unfit adviser, or even referee, for a minister or legislator; being accustomed to draw his deductions from his own particular branch of business, or apt, if he go out of it, to form a hasty judgment from first impressions. If he observe in war a tendency to raise prices, or to invigorate particular lines of trade (such as ship-owning or insurance), he will probably be led to the general inference, that, to a maritime country, war is advantageous. Our last contests having been attended with the undisputed command of the ocean, nothing more was required to satisfy the majority of merchants that our mercantile marine was in a state of equal ascendancy: they took *à la lettre* the custom-house reports of our annual exports, without observing how much was to be deducted for the progressive depreciation of money, or how surely we were laying the foundation of foreign rivalry, by submitting to enormous taxation, and a consequent enhancement of provisions and labour. Again, when in 1807 the long continuance of war had given a serious wound to our trade and navigation, a majority of the merchants ascribed it not to the true cause, but to the undermining competition of the Americans. Their range of reflection was not such as to enable them to perceive that, by overturning the prosperity of the latter, we should sap the foundation of our own; and that every million which we prevented our Transatlantic neighbours from adding to their capital, was so much withdrawn from a fund devoted to the increase of the productive industry of Britain. Hence our unfortunate *Orders in Council*, the main cause of the overthrow of our exchanges with the Continent, of the increase of our expences in Spain and Germany, of our war with the United States, in short, of the long continuance of our sufferings since the peace. Can it be necessary to add more to demonstrate the impolicy of being guided in general questions by mercantile men? Let them confine themselves to the sphere of practical exertion: a sphere sufficiently wide to gratify the most ardent or patriotic, assured, as they well may be, that it is not only the road to individual wealth, but the means of furnishing a most effectual addition to the stock of national power.

Comments
Bad Effects
of long Cre-
dit.

Nothing would more conduce to the prosperity of trade than the adoption of the plan of doing all wholesale business for ready money, and the relinquishment of that habit of long credit which prompts to unguarded enterprise, and has for so many years been the principal cause of crowding the columns of our Gazettes. Hopes of a change in this respect may now be confidently entertained, partly from the greater plenty of money consequent on a state of peace, and more from the general conviction of the impolicy of limiting the rate of interest by law. The repeal of the restrictive statutes will probably be founded on a partial view of the case, and more particularly on the desire of enabling landholders to obtain loans, without resorting to the disreputable alternative of annuities. Its effects in trade have been little anticipated, but we venture to predict that the extent of beneficial change will far outrun the expectation of the supporters of the measure.

In order to show the results of long credit, it is necessary to go a considerable length into practical illustration, and to apprise those of our readers who are not in the mercantile line, of the real situation of the majority of our manufacturers and export merchants. A manufacturer on the present footing receives orders in the course of a year from twenty or thirty mercantile houses; the goods to be exported probably to the West Indies, the United States, the Spanish Main or Brazil; the understood term of credit fourteen months. The manufacturer does not receive the orders from abroad; he has an intermediate guarantee—that of the exporting merchant. Still the risk is considerable, but he naturally hopes for the best, and is unwilling to decline an order when it comes to him from a quarter of respectability. Now, by mercantile respectability, we must apprise our readers that they are to understand integrity, and the intention of acting up to engagements; the power of doing so, especially at a remote date, is a very different question, and is, in general, possessed in a much smaller degree than the public imagines. The trader, whose capital is L. 30,000. will not scruple to ship goods to the value of L. 40,000; first, in the hope so general among merchants, of realizing a handsome profit; and next, in the confidence that, should the foreign market be dull, and should delays occur in obtaining returns within the given time, his credit will procure him indulgence for several months, at the end of which the expected remittances can hardly fail to arrive. He may, and in general does, go on for several years without much embarrassment, receiving, indeed, less than he sends out, but assured that all has been well sold, and cannot fail to be soon realized. He thus goes on, pleasing himself at every balance of his books with the seeming profit, and only regretting that hitherto that profit has not been tangible, since it exists only in the shape of a debt, due by his Trans-Atlantic correspondents. He continues, however, under a favourable expectation of their making up for past deficiencies; and flatters himself that the delay that has hitherto occurred has resulted from partial or temporary causes. He begins to find himself somewhat straitened for funds, but has as yet little difficulty in obtaining relief from a monied friend, or a prolonged credit from the

manufacturers. His correspondents continue to write in a strain of confidence, and to call for more goods, which, if he be of a confiding character, will lead him to extend the annual amount of his shipments; but, at all events, he is obliged to continue a certain supply for the sake of keeping up the assortment of stock. Still he finds that, year after year, a larger portion of his capital remains on the other side of the Atlantic, and that his correspondents, however desirous (for we by no means put an extreme case), are unable to prevent the accumulation of debt, because they are, in like manner, left unpaid by the inhabitants of the country. To go to law would be of no avail, since it is the policy of almost every government in a recently settled country to favour the debtor, and to give him the means of retaining capital in his hands. Affairs now come to be serious with the exporter; the manufacturers and other creditors cannot or will not give farther time, and demand an explanation of his circumstances. This explanation takes place, and serves to show that their debtor is a man of honour, with more assets than debts; but the latter are certain, while the former are at the distance of 3000 miles. The consequence is a grant of time; an allowance to the debtor of two, three, or four years, to act under letter of licence, in the hope of making up that which cannot, it is evident, be performed sooner. This is, in general, both the most wise and most liberal course; still it is not often found to succeed, because the foreign debts cannot be realized in climates where life is held by so uncertain a tenure, where respectable agents are so rarely found, where buyers of goods have so little capital, and, above all, where the law allows so little support to the creditor. A few of the promised instalments are probably made good, but, in general, the merchant recognises the impracticability of fulfilling the remainder, and finds it eventually necessary to submit to the mortification of a bankruptcy.

Such has been the case of a very large proportion of the mercantile establishments in our outports, and even in London, during the last twenty years. Distressing, indeed, has been the catalogue as exhibited in the Gazette, particularly since 1810; but even at present the public are not aware of the real extent of the failures, because in many the arrangements are private. Add to this, that the attention of the public is seldom so long directed to one object as to lead to conclusions of the general nature now mentioned. The fact, however, is, that old establishments, we mean houses which go back for half a century or more, are almost the only ones which have escaped insolvency. Among houses of recent origin, what a succession of failures has taken place in Liverpool, Glasgow, Manchester, Birmingham, and even in London! But we forbear to enlarge on this distressing picture, and turn for relief to countries which have been exposed to considerable shocks, but which have never conducted business on the system of long credit.

If we begin with Holland, we find that bargains in that country were, in its better days, almost always made for ready money, or for so short a date as six weeks or a couple of months; profits were small in their ratio, but the quickness of returns

Holland a Country of short Credit.

Commerce. made them eventually large; failures were rare, even in so distressing an era as the occupation of their country by the French, which began in 1795, and involved, from the outset, a stoppage of maritime intercourse with all their possessions in India and America. The consequence of this stoppage was a decay of trade, a suspension of various undertakings, a scarcity of work, a miserable dullness in the sale of goods; all leading, in the first instance, to diminished income, and eventually to encroachment on capital; but, amidst all this distress, the failures were surprisingly few,—fewer, indeed, than occur in Britain in any ordinary season. Another example, equally replete with instruction, is the present state of France, where, ever since the invasion of 1814, there has been very little credit given; and where business has been done for ready money from necessity, exactly as it was formerly done in Holland from choice. Of late years, one great misfortune has followed another in that country. The return of Bonaparte from Elba, the second invasion of the allies, the heavy contributions, the expence of the Army of Occupation, and, worst of all, the bad harvest of 1816, seemed to shake property to its foundation. There prevailed, in fact, a general discouragement among the upper ranks, and a great deal of wretchedness among the lower, trade being at a stand, and stocks of goods lying unsold in shops or warehouses for years; still bankruptcy was and is exceedingly rare. All this shows what a satisfactory prospect we may anticipate when we come the length of transacting the greater part of our business for ready money.

Beneficial
Effects that
would result
from the
Abolition of
the Usury
Laws.

5. Yet we are far from recommending any law or measure to enforce that object; the evident advantage of the plan will not fail to secure its adoption, whenever we succeed in obtaining the removal of the grand legal impediment. What, it may be asked, do we mean by this impediment? We answer, that law which imposes a forced limitation on the rate of interest. By that law, a capitalist is not permitted to take more than 5 per cent. interest for the loan of money, whatever may be the risk. If he exceed that limit, he renders himself liable to the ruinous penalties of the laws, or to all the hazards attendant on a mercantile partnership, hazards which affect not merely the sum advanced, but the whole of his fortune. He is consequently obliged to seek other means of employing his money; vesting it in the public funds; confining it to the discount of the best mercantile bills; lending it on mortgage, and not unfrequently sending it out of the country tempted by the higher interest given in France and other parts of the Continent. Now there are, in all mercantile cities, and particularly in London, a body of capitalists, who are too well aware of the hazards of trade to expose their whole property to them, but who would gladly bring forward a fourth, a third, or even a half of it, in the hope of realizing an increased income, and for the sake of enjoying that gratification which attends active employment, and the indulgence of hope and prospect. Men of business are not capable of absolute retirement; the object of their latter years is to lessen anxiety, not to withdraw entirely from the scene of

activity. Their habits, their calculations, their attachments, all keep them in connection with their early friends, and with the scene of their exertions: the point, therefore, should be not to urge them, as the law has hitherto done, to an abrupt dereliction of mercantile chances, but to enable them to continue them in a greater or lesser degree, as may suit their circumstances or individual character.

Such would be the effect of a change in regard to the lender. Let us next advert to the situation of the borrower. There is a general disposition in merchants to carry their business beyond the extent of their personal capital, a disposition which has no doubt frequently been carried to excess, but which ought by no means to be subjected to unqualified censure. No one can pretend to draw a general line of distinction between laudable enterprise and sanguine speculation; it must be left to the decision of the individual, and of the connections who support him. Often will it happen that a man of talent and judgment finds his personal funds inadequate to enter on the field of fair and legitimate enterprise, or to procure him an adequate share in an established business. We are perfectly aware that in London, men of this description frequently succeed, in the middle or latter part of life, in becoming partners in well established concerns; but it is equally true, that many of them are doomed to a different lot, and pass their life in unproductive routine. Counting-house occupation is carried on in comparative retirement; it presents no opportunities of public appearance as in the profession of the Law, and years pass away without bringing an individual into notice with others than his employers and immediate connections. Hence the importance of removing a great impediment imposed by our usury laws, the effect of which is to prevent the capitalist from coming forward to the aid of a promising beginner.

Let us next say a few words on the situation of our manufacturers. A disposition to enterprise existing strongly among our export merchants; the result is, that business must be done; and, if not for money, for credit;—on whom shall the responsibility fall? “Not,” says the law, “on the capitalist; if he take more than five per cent., he shall subject himself to the penalties of usury, or he shall risk his whole fortune by a partnership.” The spirit of adventure is not, however, to be restrained; orders arrive, and goods must be supplied; the burden of credit is then made to devolve upon the furnishers of these goods, whether manufacturers or wholesale venders. It would be in vain for these persons, particularly the former, to urge that it is entirely out of their line to judge of the stability of the merchant, residing, as he generally does, in a different quarter, and connected with people to whom they are strangers. The case is peremptory, “if you do not give credit, we must apply to others who will.” The alternative of the manufacturer, or wholesale vender, is then to make such additional charge on his goods, as may prove an indemnity for his average loss; a charge amounting in general to 12, 15, or 18, per cent., and which, besides its magnitude, has the unfortunate effect of pressing equally on the solvent and insolvent buyers. How different will be the case when the ca-

Commercé. Capitalist shall find himself at liberty to stipulate a rate of interest proportioned to his risk! He will look around the circle of his mercantile friends for a man of honour and prudence, offer to supply his deficiency of pecuniary means, receives such security as the case admits of, and bargains, not for a share in the adventure, but for an extra interest, and the repayment of his money at a remote date. The important point once adjusted, what does the merchant do?—He goes to the manufacturer, not as at present, to ask credit for twelve or fourteen months, but with ready money in his hands. What a surprising difference does this make to the manufacturer! instead of adding, and being in fact obliged in self-defence to add the large sum mentioned above, he sells and sells cheerfully at so trifling a profit as $2\frac{1}{2}$, 2, or $1\frac{1}{2}$ per cent. for ready money. Nothing can be more erroneous than to suspect a real man of business of aiming at a high profit; security, quick returns, and exemption from perplexed accounts, are his objects; and, when paid in cash, he is saved so much trouble and uncertainty, that his demand becomes extremely moderate. The manufacturer looks for no other indemnity than, first, a reimbursement of his outlay for the raw material; next, a small consideration for the expence of his establishment in rent and salaries, and, finally, a still smaller for his personal trouble. An enlarged income is, no doubt, his eventual hope, but that, he is conscious, must arise not from swelling his charge, but from *extending the scale of his business*. Observe the admirable effects of the ready-money plan on the progressive ramification of business,—it affords the manufacturer the power of purchasing the raw material for ready-money; he obtains it at a reduced price, exactly as the merchant obtains the finished article from him; accounts are greatly simplified; a briskness is given to mercantile transactions in all their stages; an important reduction takes place in the price of export goods, and we become much more able to stand the competition of foreign manufacturers. It is, moreover, no insignificant advantage that our traders are thus enabled to know their real situation, and to be aware of the *limits of their income*, while assured of the security of the principal: they thus become better calculators, and avoid those expences which steal so naturally on the mind of a person accustomed to view the profits through a magnifying medium, and which are one of the great causes of bankruptcy being so much more frequent among merchants than in the other classes of society.

Among other advantages resulting from the adoption of such a plan, would be that of saving a heavy expence, incurred at present by many houses in the collection of debts. A travelling clerk can hardly cost less than £. 400 or £. 500 a-year; and, in the metropolis, where such collections are made by a partner or principal clerk, a deal of precious time is lost in repeated calls on the one hand, and on the other in expedients to postpone the day of settle-

ment. We should no longer see new establishments seeking to procure orders by outbidding their neighbours in offers of prolonging credit; and we might hope to witness the gradual abandonment of certain very costly, and by no means effectual methods of courting business. We allude to the habit of expensive living as a proof of property, and as a means of attracting connections. All such expedients are flattering in the eyes of the inexperienced beginner, but their inefficacy is well known to the veteran merchant, who will not hesitate to declare that were his career to be renewed, he would make a point of avoiding them as well as almost all the steps so frequently embraced for the sake of *pushing business*. In the mercantile, as in other lines, the means of success are few and simple; not easy of attainment, indeed, and requiring, above all, long continued perseverance, but less varied and complicated than a youthful mind is apt to imagine. Analyze the true qualities of a man of business, you will find them reduce themselves to fairness, vigilance, and steadiness,—fairness, exemplified in declaring his terms at once, and in never deviating from an engagement—vigilance in superintending his assistants, his clerks, and his workmen—and steadiness in following up his proper line, year after year, without turning to the right or left in pursuit of speculative advantages. These, plain as they are, form the true virtues of mercantile life; the man who is known to possess them will be at no loss for connections, and may safely leave to others the task of seeking a reputation for hospitality by their mode of living, of activity by the frequency of their solicitations, or of liberality by an unusual prolongation of credit.

In reasoning with such confidence on the good effects of so simple a measure as that of laying open the rate of interest, we may be charged with going too far, and with indulging in sanguine anticipations; but no one can pretend to foresee or to limit the extent of good arising from restoring business to its free course. Again, if we are thought to lay too much stress on the degree of aid to be derived by a supply of capital to the mercantile body, our answer is, that merchants are, in general, much shorter of capital than the public imagine, and that the rate of interest is low only for stock, lands, or other undoubted securities. Such was, in a great degree, the case in 1809 and 1810, yet merchants, it is well known, were far from experiencing a pecuniary overflow. Finally, it may be objected, that money will not unfrequently be lost by the capitalist from his being pressed to join in incautious speculations. All enterprise is necessarily exposed to hazard; but the probability is, that the loss will be much less to the capitalist than it at present is to the manufacturer, the latter being wholly in the dark as to the circumstances of his various debtors, while the former has evidently good means of information as to the one or the two persons whom he may chuse to entrust with his money. (D. D.)

Commercé.

CONCHOLOGY.

Conchology. **CONCHOLOGY** is that branch of Natural History, which makes us acquainted with the form and structure of shells, enables us to classify them according to their external characters, and prepares us for the examination of the Molluscous animals to which they afford protection. It has frequently been confounded with Crustaceology, especially by the older writers on Natural History, who were in a great measure ignorant of the organization of the less perfect animals, and incapable of fixing the limits of kindred tribes. But between testaceous and crustaceous animals the line of separation is well defined, whether we attend to the composition of the covering, or to the structure of the contained animal. The *shells* of the former are principally composed of carbonate of lime, united with a small portion of animal matter in the form of gelatine or coagulated albumen; the *crusts* of the latter, along with animal matter and carbonat of lime, contain also a considerable quantity of phosphat of lime. The difference, however, between the two tribes, is much more strongly marked, when we examine the animals to which these coverings belong. The testaceous animals are remarkable for the softness of their bodies, the continuity of their parts, the simplicity of their mouth, and the permanency of their attachment to their calcareous dwellings. The crustaceous animals, on the other hand, have a fibrous texture, articulated members, complicated organs of mastication, and, at stated periods, renew their coverings. Testaceous bodies have likewise been confounded with the *Echinodermata* (a class which includes the sea urchins and the star-fish) not only by Aristotle, but by many modern naturalists. But the crusts with which these animals are covered, contain the same ingredients as are found in the coverings of the crustacea; and the animals themselves are furnished with prehensile tentacula. Hence they are essentially different from the testacea, and appear to be more nearly related to the Zoophytes, with which Rondeletius, and, after him, Cuvier, united them.

In taking a view of this extensive subject, we propose to confine our remarks to the consideration of testaceous bodies as objects of utility—of amusement—of scientific arrangement,—and lastly, as objects of interest to the geologist. In the body of the work the reader will find many valuable synoptical tables of the systems of different authors, and an extensive list of species, with their characters, arranged according to the Linnean method.

Testaceous Bodies considered as Objects of Utility.

Although testaceous bodies furnish many articles of value to man, scarcely any Conchologist has taken the trouble to enumerate the different purposes to which they have been applied, or to point out in what manner their usefulness might be increased. To the savage, shells furnish some of his most important instruments. They often answer all the purposes of a knife, and are extensively employed as a

substitute for iron: with pieces of the more solid bivalves he points his arrows, and forms his fish-hooks. Even when farther advanced in civilization, the canalculated univalves sometimes constitute the rustic lamp, while the larger scallops are employed by the dairy-maid to skim her milk and to slice her butter. From the mother-of-pearl shell many useful and ornamental articles are fabricated; and calcined shells were formerly esteemed by Physicians as absorbents; and are still regarded by the farmer as furnishing a valuable manure.

Shells thus appear to be of some importance in the arts of life; but the animals contained in these shells are of far greater value. As articles of food, shell-fish are extensively employed by the poor, and even hold a conspicuous place at the tables of the rich. In many places, they in a great measure support the children of our maritime population, and, in the Western and Northern Islands of Scotland, have, in years of scarcity, prevented the death of thousands.

The kinds chiefly used in this country, as articles of subsistence, are bivalves, belonging to different genera. Among these the *Oyster* (*Ostrea edulis*) holds the most distinguished place. This shell-fish is very widely distributed in nature, being found in the seas of Europe, Asia, and Africa. But, since the days of the luxurious Romans, the oysters of Britain have been held in the highest estimation. They are found on various parts of our coasts, from the southern shores of England, to the sheltered bays among the Zetland Islands. They prefer a rough or rocky bottom, in from five to twenty fathoms water. They are fished up with a dredge and an open boat; sometimes, when in shallow water, with a rake or tongs. They are either conveyed directly to the market, or are placed in artificial ponds of sea water, where they increase in size, and acquire a fine green colour. In England this process of *fattening*, as it is termed, is chiefly conducted at Colchester, but the oysters are obtained from the little creeks between Southampton and Chichester. This fishery on the coast of England is supposed to give employment to ten thousand people, so that, independent of the addition which it makes to the articles of subsistence, it must be regarded as a valuable nursery for seamen. As an article of food, oysters are light and easy of digestion, and may be eaten in great numbers without inconvenience. They are used either raw or when pickled. In the last form, they are sent to different parts of the country, and even constitute an article of export. In Scotland, the principal oyster fishings are in the Firth of Forth; but we trust the period is not far distant, when the proprietors on the western coast of Scotland and the Hebrides will propagate this shell-fish more extensively on their shores and sheltered bays. Places fitted for their growth are every where to be met with; they require no superintending care; they would soon furnish an

Bivalve.
The Oyster.

Shells as
Objects of
Utility.

Conchology. esteemed dish to their tables, and form a valuable addition to their trade.

Mussel. The next shell-fish, in point of importance as an article of food, is the *Mussel* (*Mytilus edulis*). This animal is equally widely distributed as the oyster, and is found upon our coast in the greatest abundance. It is gregarious, being found in extensive beds, which are always uncovered at low water. It is found likewise in the crevices of the rocks. In this fishery women and children are chiefly employed, and they detach the mussels with an iron hook from the beds or rocks to which they adhere by means of fine cartilaginous threads. In this country they are conveyed directly to the market; but in some places of France they are kept for a time in salt ponds, to fatten like the oyster, into which, however, they admit small quantities of fresh water. The flesh of the mussel is of a yellowish colour, and considered very rich, especially in autumn, when it is in season. It is eaten in this country either boiled or pickled, seldom in soup. To the generality of stomachs it is difficult to digest, and to many constitutions it is deleterious. It is, however, in the spring, during the spawning season, that the greatest danger is to be apprehended. This noxious quality was long considered as occasioned by the *pica crab*, which is often found within the shell of mussels. It is now with more propriety attributed to the food of the mussel, which, at certain seasons, consists chiefly of the noxious fry of the star-fish; and likewise to a disease to which the animal is subject in spring, under the influence of which it melts away, and falls from the rocks. Besides being useful to man as an article of subsistence, the mussel supplies the fisherman with one of his most convenient and successful baits. It is keenly taken both by cod and haddock. To the cod-fish, however, the animal of the horse-mussel (*Modiola vulgaris*) is more acceptable.

Cockle. The *Common Cockle* (*Cardium edule*) would deserve a place in preference even to the mussel, were it not exclusively confined to our sandy coasts and bays. It is found lodged in the sand, a few inches below the surface, its place being marked by a small depressed spot. Women and children easily dig up this shell-fish with a small spade. Cockles are sold by measure, and eaten either raw, or boiled, or pickled. They are deservedly esteemed a delicious and wholesome food in this country, although in France they are little regarded. They are in season during March, April, and May, after which they become milky and insipid. They are not generally used as a bait.

Razor-Fish. Two kinds of *Razor-fish* (*Solen siliqua* and *ensi*) are in many places of this country used as food. In Scotland they are indiscriminately termed *Spout-fish*. They are found upon most of our sandy shores, buried about a foot or two below the surface, and near to the low water mark. Their place is known by a small hole in the sand. As it is rather a laborious operation to dig them out, Bose informs us, that the fishermen of France throw a small pinch of salt into their holes, which always remain open by the action of the respiratory organs; that they speedily rise to the surface, and are thrown out by an iron instru-

ment made for the purpose. The fishermen believe **Conchology.** that it is the salt which they wish to avoid; but it is conjectured, with greater probability, that the presence of the saltier water, which is thus formed by the solution of the salt, makes the animal suppose that its hole is again covered with the tide. This shell-fish was esteemed by the ancients as a great delicacy. When boiled or fried, it is certainly a very palatable morsel. When kept for a few days, it forms an excellent bait for haddock or cod, and may even be employed for that purpose in a fresh state.

Several species of *Gapers* (*Mya*) are used as food **Mya.** both in Britain and on the Continent, as the *Mya arenaria*, known to the fishermen about Southampton by the whimsical name *Old Maids*. These shells reside in the mud or shingle on the shore, and a few inches below the surface. In some parts of England and Ireland, they are much used, but, though common in Scotland, they are never sought after. Another species, the *Mya truncata*, is also very common on the coast. It prefers a hard gravelly bottom, in which it lodges near low water-mark. The inhabitants of the northern islands call it *Smaoslin*, and employ it when boiled as a supper dish. It is not so delicate as some of the shell-fish which we have noticed, but it is by no means unpalatable. The *Mya declivis* of Pennant is, according to that author, very plentiful in the Hebrides, and eaten by the gentry of that country. We suspect that he should have referred to the *Mya truncata*. These shells furnish very good baits to the fisherman.

There are several bivalve shells, besides those which **Scallops.** we have mentioned, employed on our coasts as articles of subsistence. The *Scallop* (*Pecten*) was held in high estimation by the ancients, and still is sought after in Catholic countries. The *Pecten maximus* is frequently used in England. It is found gregarious in moderately deep water, and is taken up by the dredge. It is pickled and barrelled for sale, and esteemed a great delicacy. The fishermen suppose that they are taken in the greatest quantity after a fall of snow. Another species, the *Pecten opercularis*, is employed for culinary purposes in Cornwall, where it is known by the name of *Pills* or *Queens*. In the Firth of Forth this species is frequently dredged up along with oysters, but it is thrown, by the Newhaven fishermen, to the dunghill, along with sea urchins and star-fish. To this list we might add the *Maetra solida*, which is used as food by the common people about Dartmouth; and the *Venus pallastria*, called by the inhabitants of Devonshire Pullet, and eaten by them, and known to the inhabitants of the Northern Islands by the name of Cullyock, and there used as a bait. According to Bruguiere, the *Stromia ephippium* is used as food at Languedoc, and is there considered as preferable to the oyster.—But it is now time that we turn our attention to the univalve shells, in order to ascertain their value in an economical point of view.

The common *Periwinkle* (*Turbo littoreus*) is, in **Univalves.** this country, more extensively used as food than any **Periwinkle.** of the other testaceous univalves. This shell is easily gathered, as it is found on all our rocks which are left uncovered by the ebbing of the tide. Children

Conchology. are principally employed in this fishery, and the shells are sold by measure. They are in general used after being plainly boiled, and are consumed in great quantities by the poor inhabitants on the coast. The *Nerita littoralis* is also frequently gathered along with the periwinkle, as it frequents the same situations. It is, however, much smaller, and its flesh is not reckoned equally good.

Limpet. The *Limpet* (*Patella vulgata*) is equally abundant as the periwinkle, and frequents the same situations on the rocks. Although used by the ancients as an article of food, it is seldom brought to market in this country. Among the villages along the coast of Scotland this shell-fish is frequently used, and its juice, obtained by boiling, mixed with oatmeal, is held in high estimation. It is considered in season about the end of May. The chief excellence of the limpet, however, is as a bait. It is very easily obtained from the rocks, from which the fishermen detach it with a knife, and it is eagerly seized by all the littoral fish which are sought after. To the haddock it is very acceptable.

Snails. Several species of *Snails* (*Helix*) are employed for culinary purposes. The largest of these, the *Helix pomatia*, was a favourite dish among the Romans, who fattened them with bran sodden with wine. They are still used in many parts of Europe during Lent, after having been fed with different kinds of herbs. This species was originally imported into Britain from Italy, and turned out in Surry, where it has readily multiplied. The *Helix hortensis* has also been employed as food. But, we believe that these two species are chiefly used medicinally, being administered in consumptive cases. The small species of the genus are the favourite food of the birds of the thrush kind, either in a wild or confined state.

Welks. The other univalves which we shall notice are of inferior importance as articles of subsistence. The *Murex despectus*, the largest of the British turbinated shells, is frequently dredged up with oysters, and, according to Pennant, "is eaten by the poor, but oftener used for baits for cod and ray." It is probably the same species which is noticed by the Reverend William Fraser, in his view of the Parish of Gigha and Cara in Argyleshire, Vol. VIII. p. 48. of the *Statistical Account of Scotland*. He says it is a large white welk called *buckie* or *dog-welk*, and used as a bait for cod. The method of obtaining these shells for bait being ingenious, and making us acquainted at the same time with several new habits of the animal, we shall here insert it. "At the beginning of the fishing (says Mr Fraser) a dog is killed and singed, and the flesh, after rotting a little, is cut into small pieces, and put into creels or baskets made of hazel-wands for the purpose. These creels are sunk by means of stones thrown into them. The flesh of the dog, in its putrid state, is said to attract the welk, which crawls up round the sides of the basket, and getting in at the top, cannot get out again, owing to the shape of it, which is something like that of the wire mouse-trap. After the first day's fishing, the heads and entrails of the cod, with skate and dog-fish, are put into the creels, which are visited every day, the welks taken out, and fresh bait of the same kind put in, there be-

ing no more occasion for dogs' flesh." The *Buccinum undatum* and the *Purpura lapillus* are also employed as bait, and in years of scarcity as food.

This list of culinary shell-fish is far from complete, even in so far as it is a British list. The uses of these molluscous animals have seldom been taken notice of by Conchologists since the days of Schonvelde, more attention having been directed to the formation of new systems of arrangement, and to the discovery of new species, than to the habits and uses of those already known.

Independently of the food which we thus obtain from testaceous animals, they furnish us with the *pearl*, one of the most beautiful ornaments of dress. This substance, equally prized by the savage and the citizen, is composed, like shells, of carbonate of lime, united with a small portion of animal matter. Pearls appear to be exclusively the production of the bivalve testacea. Among these, all the shells having a mother-of-pearl inside, produce them occasionally. But there are a few species which yield them in greater plenty, and of a finer colour. The most remarkable of these is the *Avicula margaritifera*. This shell, which was placed by Linnæus among the mussels, is very widely distributed in the Indian Seas; and it is from it and another species of the same genus, termed *Avicula hirundo*, found in the European Seas, that the pearls of commerce are procured. The *Pinna*, so famous for furnishing a byssus or kind of thread, with which garments can be manufactured, likewise produces pearls of considerable size. They have seldom the silvery whiteness of the pearls from the *Avicula*, being usually tinged with brown. But the shell which in Britain produces the finest pearls, is the *Unio margaritifera*, which was placed by Linnæus in the genus *Mya*. It is found in all our alpine rivers. The Conway and the Irt in England, the rivers of Tyrone and Donegal in Ireland, and the Tay and the Ythan in Scotland, have long been famous for the production of pearls. These concretions are found between the membranes of the cloak of the animal, as in the *Avicula*, or adhering to the inside of the shell, as in the *Unio*. In the former case, they seem to be a morbid secretion of testaceous matter; in the latter, the matter seems to be accumulated against the internal opening of some hole with which the shell has been pierced by some of its foes. Linnæus, from the consideration of this circumstance, endeavoured, by piercing the shell, to excite the animal to secrete pearl; but his attempts, though they procured him a place among the Swedish nobility and a pecuniary reward, were finally abandoned; the process being found too tedious and uncertain to be of any public utility. The largest pearl of which we have any notice, is one which came from Panama, and was presented to Philip II. King of Spain, in 1579. It was of the size of a pigeon's egg. Sir Robert Sibbald mentions his having seen pearls from the rivers of Scotland as large as a bean.

Besides yielding us a variety of wholesome food, these and valuable ornaments, testaceous animals supply us with a beautiful dye. The *Purpura* of the ancients, according to the opinion of Rondeletius, confirmed by the observations of Cuvier, was chiefly extracted

Conchology. from the shell termed *Murex brandaris*. Since the introduction of the cochineal insect, the use of this dye has been superseded, so that we are now in a great measure ignorant of the process which the ancients employed to extract it. In Britain there are several kinds of shell-fish, which furnish a dye of this sort, but these are seldom sought after. Cole, in 1685, published a method of obtaining it from the *Purpura lapillus*, to which Montagu, in the Supplement to *Testacea Britannica*, has added several important directions. When the shell is broken in a vice, there is seen on the back of the animal, under the skin, a slender longitudinal whitish vein, containing a yellowish liquor. When this juice is applied to linen, by means of a small brush, and exposed to the sun, it becomes green, blue, and purple, and at last settles in a fine unchangeable crimson. Neither acids nor alkalies affect its colour, and it may be conveniently employed in marking linen, where an indelible ink is desirable. The *Scalaria clathrus* (*Turbo clathrus* of Linnæus) also furnishes a purple liquor of considerable beauty, but it is destructible by acids, and gradually vanishes by the action of light. The *Planorbis corneus* likewise yields a scarlet dye, but of still less permanency than the *scalaria*, as all attempts to fix it have hitherto proved ineffectual.

We cannot conclude this chapter without remarking, that the study of testaceous bodies rises in importance as we perceive its utility. When we are told, that searching for shell-fish, and conveying them to the market, give employment to a British population of upwards of 10,000; that these animals furnish nourishing food to innumerable families, and in years of scarcity prevent the horrors of famine; we will be disposed to regard with a favourable eye the labours of that Conchologist, who examines the structure and economy of those animals, that, from a knowledge of their nature, he may render them still more subservient to our purposes.

Testaceous Bodies, considered as Objects of Amusement.

Shells as Objects of Amusement. In the preceding division of our subject, we have considered testaceous bodies as applicable to various useful purposes, and expressed our regret, at the same time, that no one qualified for the task had ever bestowed on economical Conchology an attentive examination. We cannot therefore consider the present condition of the science as the result of the labours of its practical admirers. The lovers of this study, as an agreeable amusement, have at all times been numerous, from the days of Lælius and Scipio to the present time; and it is to their exertions, as collectors, that the science is principally indebted for its present state of improvement. The colours of shells are often so intensely vivid, so finely disposed, and so fancifully variegated, that, as objects of beauty, they rival many of the esteemed productions of the vegetable kingdom. In their forms they likewise exhibit an infinite variety. While some consist merely of a hollow cup or a simple tube, others exhibit the most graceful convolutions, and appear in the form of cones, and spires, and turbans; and in another division, shaped like a box, all the varieties of hinge are exhibited, from that of simple

Conchology. connection by a ligament to the most complicated articulation. The forms of shells are indeed so various, and many of them so elegant, that a celebrated French Conchologist warmly recommends them to the attentive study of the Architect. "Or," says Lamarck, "comme l'extreme diversité des parties protuberantes de la surface de ces coquilles, ainsi que la régularité et l'elegance de leur distribution, ne laisse presque aucune forme possible dont la nature n'offre ici des exemples; on peut dire que l'architecture trouveroit dans les espèces de ce genre (*Cerithium*) de même que dans celles des pleurotomes et des fuseaux, un choix de modèles pour l'ornement des colonnes, et que ces modèles seroient très dignes d'être employés." (*Annales du Mus.* Vol. III. p. 269.) In this country, however, no such recommendation is necessary, as many of our beautiful ornaments of stucco, particularly for chimney-pieces, are copied from the univalve testacea, and are greatly admired.

But shells, even with all their beauty and elegance, would never have acquired so much importance in the eyes of amateurs, had their forms been as difficult to preserve as the external coverings of the higher classes of animals. It is both a tedious and a difficult operation to preserve a quadruped, a bird, or a fish, as a specimen for the cabinet, and even when the task is completed, it is but of temporary duration. A slow but certain process of dissolution is going on, which, though invisible for a time to the owner, gradually destroys the finest collection of these objects. The very changes of the atmosphere, combined with the attacks of insects, accelerate the destructive process. But with shells the case is very different. Composed of particles already in natural combination, they do not contain within themselves the seeds of dissolution, so that for ages they remain the same. Besides, all that is in general necessary to prepare a shell for the cabinet, is merely to remove the animal. When the shell is covered with foreign matter, we must wash it away with a brush in soap and water; and it is frequently necessary to steep the shell for some time in fresh water, to extract all the salt water which may adhere to it. After being properly dried it is fit for the shelf of the cabinet, and stands in no need of anxious superintendence.

Polishing of Shells. Amateurs are seldom contented with the simplicity of nature. Vitiating their taste by a fashion which abides by no rules, they attempt to improve even her most elegant productions, and delight to exhibit in their cabinets some of the efforts of their art. As such are in search of innocent amusement, we mean not to dispute about the propriety of their conduct, but rather shortly to mention, for their edification, the method generally in use to improve the beauty of testaceous objects. Many shells, it is true, naturally possess so fine a polish, that no preparation is considered necessary before placing them in the cabinet. Such are the *Cyprea*, *Olivæ*, and the greater number of what are termed *porcellaneous shells*. In general, however, it happens that, when shells become dry, they lose much of their natural lustre. This may be very easily restored, by washing them with a little water, in which a small portion of gum arabic has

Conchology.

been dissolved, or with the white of an egg. This is the simplest of those processes which are employed, and is used not only by the mere collector, but by the scientific Conchologist. There are many shells of a very plain appearance, on the outside, by reason of a dull epidermis or skin with which they are covered. This is removed by soaking the shell in warm water, and then rubbing it off with a brush. When the epidermis is thick, it is necessary to mix with the water a small portion of nitric acid, which, by dissolving a part of the shell, destroys the cohesion of the epidermis. This last agent must be employed with great caution, as it removes the lustre from all the parts exposed to its influence. The new surface must be polished with leather, assisted by tripoli. But, in many cases, even these methods are ineffectual, and the file and the pumice-stone must be resorted to, in order to rub off the coarse external layers, that the concealed beauties may be disclosed. Much address and experience are necessary in the successful employment of this last process. But it must be confessed that the reward is often great. When thus prepared, even the common mussel is most beautiful.

The arrangement of shells in a cabinet must depend, in a great degree, on the taste and fortune of the collector. If ornament is the object in view, it will be indispensably necessary to have the shells placed in glass cases, where they may be distinctly seen. But where a collection of shells is formed for amusement, they may be kept in drawers, each species placed in a paper case, or in a cup of wood, glass, or porcelain, with a label attached, intimating its name, and the place from whence it was obtained. In this manner, both univalves and bivalves may be conveniently disposed. But, as many of the former are very small in size, it is often necessary to fix them on pieces of card, that they may be preserved, and rendered easier of inspection. Perhaps the best mode of keeping these small shells, even the microscopic species, is to have a cabinet with slips of wood made to slide horizontally. These slips may be from one to three inches in breadth, and covered with white paper. Upon the middle of these the shells are fixed, with a solution of gum arabic and a little sugar, and the name marked on the edge. In many cases, when the shells are very minute, a narrow stripe of coloured paper may be fixed along the middle of the slip, to which the shells are to be attached. When neighbouring species are thus brought together, they can be easily examined with a lens. As a convenient and neat and useful method of keeping the smaller univalves, the writer of this article can recommend it from experience. It may be used with equal advantage by the botanist to preserve the smaller Lichens.

About the end of the sixteenth century, many individuals began to form collections of testaceous bodies. The first museum of this kind, of any consequence, was begun by Benedict Ceruto, and afterwards augmented by Calceolari. An account of the specimens contained in it was published by Olivi, in 1585, and, in 1622, Chiocci published plates of the shells. After this period, in proportion as collections of testaceous bodies became numerous, vari-

Conchology.

ous works on shells made their appearance. These were not published for any scientific object, but merely to teach collectors the names of the different specimens in their museums. As works of this sort, we may mention the *Historia Naturalis* of Johnston—the *Gazophylacium Naturæ* of Petiver—the *Amboinsche Rariteitkamer* of Rumphius—and the *Wondertaoneel der Nature* of Vincent. Nay, to this list we might add many modern works, which are termed Systems of Conchology.

From the labours of this class of Conchologists the science has derived many important advantages. A taste for the study has been widely extended; the shells of distant countries and shores have been brought together; and numerous engravings of these bodies have been published. In this manner, the labours of the man of science have been greatly facilitated, and our knowledge of nature enlarged.—But it is time that we pass from the consideration of testaceous bodies, as objects of utility and amusement, to attend to the different methods which have been employed in their scientific arrangement.

Testaceous Bodies, considered as Objects of Scientific Arrangement.

Naturalists have pursued a variety of plans in their examination of this department of zoology, and have presented us with systems of arrangement founded on very different principles. Some Conchologists have attended solely to the form and structure of the shell, and have overlooked the organization of the animal inhabitant. A few have made the habits of the animal the groundwork of their systems. Others have passed over the appearances which the shells exhibit, and have confined their attention exclusively to the form and structure of the contained animal. Lastly, there have been a few who, embracing all the circumstances connected with the shell, the animal, and its habits, have constructed systems at once natural and convenient. In the following sections we propose to consider these four classes into which Conchologists may be divided.

Shells as
Objects of
Scientific
Arrangement.

SECTION I.—Systems constructed from Circumstances connected with the Characters of the Shell.

The arrangement of testaceous bodies according to their forms, is unquestionably the most obvious and the most ancient method. It was first employed by Aristotle, the father of Natural History, and even to the present day, its admirers are warm in its praise. It is with great propriety termed the *artificial method*, because the characters employed have no relation to any of the functions of animal life.

The Philosopher whose name we have now mentioned, had the merit of forming the divisions of *Μονόβυα*, or univalves, and *Διδύα*, or bivalves. He separated the turbinated univalves from such as have but an imperfect spire, and formed many genera, or rather families, which still retain the names which he imposed.

The science of Conchology made little progress for many ages after Aristotle had published his method of arrangement. Indeed, the first work of this class which merits attention, is the *Dictionarium Ostracologicum* of Major, which was published in

Conchology. 1675. To him we are indebted for the threefold division of shells into *univalves*, *bivalves*, and *multivalves*, and for an explanation of the terms then employed by Conchologists.

In the same career, but with more brilliant success, Langius followed, and, in 1722, published his *Methodus nova Testacea Marina in suas Classes, Genera et Species distribuendi*. The following character is given of this work by the intelligent and industrious authors of the *Historical Account of Testaceological writers*. (*Linn. Trans.* Vol. VII. p. 156.) "After having noticed a multitude of mere describers, we now come to an author who is not undeserving of the title of a scientific one, and whose system, so far as marine testacea are concerned (and of these alone he treats), certainly glances at the great clue to simplicity, which was afterwards so successfully and admirably seized by the great reformer of natural history in general." But Langius deserves more praise than is here bestowed upon him. Before his system appeared, the characters of the genera depended principally on the *outline*, and were of uncertain application. He remedied the defect, by directing the attention of Conchologists to the form of the mouth in univalves, and to the structure of the hinge in bivalves. Among the former, he constituted subdivisions of those *ore superius aperto*, *ore superius in canaliculum abeunte*, and *ore superius clauso*. Among the latter, the circumstance did not escape him, that some of these shells are *equivalue*, others *inequivalue*; some *equilateral*, others *inequilateral*. Hence he may be considered as the founder of the inferior divisions of the artificial method, and as having furnished, to modern Conchologists, many useful hints, of which they have availed themselves, without, however, acknowledging their origin.

Another important improvement was effected by Breynius in his *Dissertatio Physica de Polythalamis*, 1732, 4to. This consisted in separating from the ordinary univalves, such shells as possess a cavity divided by partitions into several compartments, and in forming them into a division, which he termed *Polythalamium*. These shells are now called *Multilocular*.

The system of Tournefort, which was published by Gualtieri, in his *Index Testarum Conchyliorum quæ adservantur in Museo Nicolai Gualtieri, Philosophi et Medici, Florentini*, 1742, well deserves an attentive perusal. In his observations on the bivalves, he drew the attention of Conchologists to an important character, and one of easy application, having observed that, in some genera, the valves do not close or unite all round, but that, at certain places, the shell remains in part open. Such shells, in modern language, are said to *gape*.

The system of the celebrated Linnæus, which ought now to be mentioned, is too well known in this country to deserve particular notice. In many of the other departments of Zoology he effected the most important alterations; but his attempts to reform the science of Conchology, were far from being equally successful. To the subject he never was much attached, nor does he appear to have availed himself sufficiently of the labours of those authors

whom we have mentioned, and of others who preceded him. The primary divisions which he employed, were those which Major had established, and his genera, with a few exceptions, were those in common use. His merit as a Conchologist rests entirely on the accurately defined terms,—the concise specific characters,—and the convenient trivial names which he employed and introduced. The particular consideration of the Linnæan genera, and the subsequent changes which have been introduced into them, will form the subject of a separate section.

For some time after the publication of the *Systema Naturæ*, the illustrious Swede enjoyed a very dangerous reputation. All his arrangements were regarded as of such high authority, that it was considered impious to attempt to introduce any change; so that Conchology, according to the artificial method, remained a long time stationary. At last in France, a country which refused to submit to the fetters of the Linnæan school, several new systems were proposed, which had for their object the restoration of those well founded genera, which Linnæus, in his too great desire to simplify, had suppressed, and the accommodation of the divisions of the science to those new relations which a more extensive knowledge of species had discovered. In this number Bosc stands eminently conspicuous. In his work entitled *Histoire Naturelle des Coquilles, des Vers et des Crustacés*, and in the conchological articles of the *Dictionnaire d'Histoire Naturelle*, he has favoured the world with a detail of his system, the outline of which we shall here present to our readers:

I. COQUILLES MULTIVALVES.

1. Les unes n'ont point de charnière.

Oscabrion	Balanite
Anatif	

2. Les autres en ont une.

Pholade	Anomie
Taret	Calceole
Fistulane	

II. COQUILLES BIVALVES.

I. Equivalves.

1. A charnière sans dents.

Pinna	Moule
Modiole	Anodonte

2. A charnière garnie des dents.

A. A une dent.		Lutraire
Mulette		Petricole
Crassalette		Venericarde
Paphie		Solen
Mactre		Capse
B. A deux dents.		Sanguinolatre
a. Simple		b. Avec des surnuméraires.
Trigone		Isocarde
Tridacne		Donace
Hyppope		Cyclade
Cardite		Telline

Conchology.

Venus	D. A beaucoup de dents.
C. A quatre dents.	Nucule
Bucarde	Petonce
Meretrice	Arche
Lucine	Cucullee

II. Inequivalves.

1. A charnière sans dents.

Acarde	Peigne
Radiolite	Lime
Vulselle	Houlette
Marteau	Cranie
Huitre	Hyale
Avicule	Lingule

2. A une dent.

Came	Corbule
------	---------

3. A deux dents.

Spondyle	Pandore
Plicatule	Terebratule
Placune	Calceole

4. A plusieurs dents.

Perne

III. COQUILLES UNIVALVES.

I. Uniloculaires.

1. Sans spirale.

A. En Calotte.	B. En Tube.
Patelle	Vermiculaire
Oscane	Silicaire
	Arrosoir

2. En spirale.

A. L'ouverture entière et sans canal à sa base.

Carinaire	Helice
Halotide	Volvaire
Sigare	Bulle
Stomate	Jacinthe
Argonaute	Turritelle
Concholepas	Cyclostome
Nerite	Bulime
Natice	Sabot
Helicine	Toupie

B. L'ouverture échancrée et canaliculée à sa base.

Cerite	Vis
Pyrule	Pourpre
Rocher	Volute
Rostelaire	Ovule
Strombe	Tarrière
Buccin	Porcelaine
Casque	Cone

II. Multiloculaires.

Nautilite	Turritite
Orbulite	Baculite
Ammonite	Spirule
Planulite	Orthocère
Camerine	Hippurite
Rotulite	Belemnite.

Conchology. rangement is more methodical, and the genera are more definite, than in the Linnæan system. It unquestionably holds the first rank in the modern artificial methods.

There is a class of writers whose labours deserve some notice in this place. We allude to those who have devoted their attention to the very minute shells, so common among the sand on every sea-coast. These are too small to be examined by the naked eye, and from the instrument employed in their investigation, they are usually termed *Microscopic shells*. Plancus, in his work, *De Conchis Ariminensibus minus notis*, published in 1739, may be considered as the first who drew the attention of Conchologists to these nearly invisible objects. J. F. Hoffman, in his *Dissertationcula de Cornu Ammonis nativo Littoris Bergensis in Norvegia*, published in the *Transactions of the Electoral Academy of Mentz*, 1757, and in his essay *de Tubulis Vermicularibus Cornu Ammonis referentibus*, *ibid.* 1761, made us acquainted with various species of minute nautili produced on the northern shores. Nor did those discoveries fail to excite interest in this country. Boys and Walker devoted their attention to the subject, and gave to the world the result of their labours, in a thin quarto, entitled *Testacea Minuta varia nuperrime detecta in arena littoris Sandvicensis*, London, 1784. Other observers, equally ardent and successful, have increased our knowledge of the forms of these minute bodies, particularly Soldani, who, in his *Testaceographia ac Zoophytographia parva et microscopica*, 1789 and 1795, exhibited many figures of the minute shells of Portoferrara, &c. The late Mr Adams described the minute species which he observed on the coast of Pembroke-shire, in the third and fifth volumes of the *Transactions of the Linnean Society of London*, and other species of British growth have been investigated by the author of *Testacea Britannica*. We shall close this list with noticing the *Testacea Microscopica aliæque minuta ex generibus Argonauta et Nautilus ad Naturam Picta et Descripta*, Vienna, 1798. It is the joint production of L. A. Fichel and J. P. C. A. Moll, and merits an attentive perusal.

We are aware that such microscopic investigations are regarded by some Conchologists as useless, so that the minute species are excluded from their systems. But it is surely a strange method of proceeding in natural history, to judge of the merits or importance of species from their size. It is true that we are still ignorant of the inhabitants of those shells, and may long continue to be so; but our present knowledge of these has enabled us to fill up many blanks, to preserve some new relations, and even to draw some important conclusions.

That this sort of inquiry has in many instances been injudiciously conducted, all who are acquainted with the subject must admit. Due care has not been taken to distinguish these minute testacea from the fry of the larger shells, so that the number of species has been very injudiciously multiplied. These remarks apply to several figures of Walker, and to a still greater number of those of Adams.

In this system which we have exhibited, the ar-

Conchology. SECTION II. *Systems constructed from Circumstances connected with the Habits of the Animal.*

Systems founded on the Habits of the Animal.

The authors of the preceding class have laboured to bring to perfection the artificial system of Conchology, and have formed their arbitrary characters, independent of the habits of life of the contained animal. But the naturalists whom we have now to consider, have traced these animals to their lurking places, and arranged them according to the situation in which they reside, instead of the forms which they exhibit.

At the head of this class of Conchologists Dr Martin Lister stands preeminently conspicuous. His great work, entitled *Historia sive Synopsis Methodica Conchyliorum*, was begun in 1685, and completed in 1692. It will long remain a monument of the extensive information and unwearied diligence of its author. The following synoptical view of the work will enable our readers to comprehend its plan; the original should be consulted with care.

Lib. i. De Cochleis terrestribus.

Pars 1. De Buccinis terrestribus.

Pars 2. Cochleæ nudæ terrestres Limaces quibusdam dictæ.

Lib. ii. De Turbinibus et bivalvibus aquæ dulcis.

Pars 1. De Turbinibus.

Pars 2. De Testaceis bivalvibus fluviatilibus.

Lib. iii. De Testaceis bivalvibus marinis.

Pars 1. De Testaceis bivalvibus, imparibus testis.

Pars 2. De Testaceis bivalvibus, paribus testis.

Pars 3. De Testaceis multivalvibus.

Lib. iv. De Buccinis marinis quibus etiam vermiculi, dentalia et patellæ numerantur.

The plan followed by Sir Robert Sibbald in his *Scotia Illustrata* is somewhat different from that of Lister. He divides the Testacea into two classes, land and water shells, and the latter class he subdivides into fluviatile and marine. His inferior divisions are destitute of precision, and the number of his species limited.

The system of D'Argenville, which was so much esteemed and so long followed in France, is essentially the same with that of Lister in the higher divisions. The plan is indeed so simple, and in appearance so natural, that it has met with many admirers. It has even been useful in encouraging naturalists to study particular departments of the science, when they were prevented by their situation from devoting their attention to the whole. It is probably to this circumstance that we are indebted to Schroter for his observations on the land shells in the neighbourhood of Thangelstadt, and on the river shells of Thuringia.

The preceding arrangements, formed according to the situations in which the animals reside, and not according to their external coverings, may be considered as the first attempts at a natural method in Conchology. They serve as an introduction to a new class of authors, whose views may be consider-

ed as of a higher order, and to whose labours we shall devote our attention in the following section.

Conchology.

SECTION III. *Systems constructed from Circumstances connected with the Form and Structure of the contained Animal.*

The first attempt, of any consequence, to arrange testaceous animals according to the soft parts of their bodies, was made by Adanson, in his *Histoire Naturelle du Sengal*, published at Paris in 1757. In this system, the ancient classes of Univalves, Bivalves, and Multivalves, are employed under the titles les Limaçons, les Conques, and les Conques Multivalves.

Systems founded on the Form and Structure of the Animal.

CLASSE I. Les Limaçons.

Sect. I. Les Limaçons Univalves.

Fam. 1. Les limaçons univalves qui n'ont ni yeux ni cornes.

Fam. 2. Les limaçons univalves qui ont deux cornes, et les yeux placés à leur racine et sur leur côte interne.

Fam. 3. Les limaçons univalves qui ont quatre cornes, dont les deux extérieurs portent les yeux sur le sommet.

Fam. 4. Les limaçons univalves, qui ont deux cornes et les yeux placés à leur racine, et sur le côté externe, ou pas derrière.

Fam. 5. Les limaçons univalves qui ont deux cornes et les yeux posés un peu au dessus de leur racine et sur leur côté externe.

Sect. II. Les Limaçons Operculés.

Fam. 1. Limaçons operculés qui ont deux cornes, avec un renflement, et qui portent les yeux ordinairement au dessus de leur racine, et à leur côté externe.

Fam. 2. Limaçons operculés qui ont deux cornes sans renflement, et les yeux placés à leur racine, et sur leur côté externe.

Fam. 3. Limaçons operculés qui ont quatre cornes, dont les deux extérieurs portent les yeux sur leur sommet.

CLASSE II. Les Conques Bivalves.
